A SMALL outbreak of scarlet fever began in Oxford out Feb. 8th, 1931, seven cases being reported, ur of which came under the observation of one of (F. G. H.). All the cases were mild, and the only mmon factor was that all received their milk from e same dairy. A careful investigation by the iblic health authorities threw no light on the source infection. Of the seven cases, four had been ceiving Grade A milk supplied by the dairy, while ree had received the ordinary milk, the two supplies ing kept quite distinct. With the exception of e two cases which form the subject of this report, l made an entirely uneventful recovery and nvalescence.

CLINICAL NOTES (F. G. H.).

The cases with which this account is concerned pear to us to be unique, so that it is wise to mention l details which may be relevant.

Family history.—The parents of the children ncerned are distant cousins. On neither side is ere any history of "bleeding" or other morbid heritance, and longevity is the normal expectation f the members of both families.

Past history.—The three children in this family, girl aged 7, a boy aged 5, and a girl aged 3, were ll healthy children who had hitherto experienced nly minor ailments and escaped any of the specific evers. All three were inclined to have large tonsils nd adenoids. They had unusually liberal allowances f fresh food in the form of fruit, salads, milk, eggs, nd wholemeal bread, and spent much time in the pen air. All were dark-haired and well nourished, ith dark eyes and high-coloured rosy cheeks.

History of the cases.—On Feb. 8th the boy, aged 5, ontracted scarlet fever, the onset being marked by ever and a sore-throat. All three children had been laying together on the 8th, and the exposure of the wo sisters was obvious. The patient and his elder ister had three years previously been given prophylactic diphtheria antitoxin; therefore no anticarlatinal serum was administered in either case for fear of a serum reaction. The younger sister was given a prophylactic dose of anti-scarlatinal serum, and protected. On Feb. 12th the elder sister, aged 7, developed scarlet fever. The two children were then nursed in the same room, the beds being at least eight feet apart. In each case the scarlet fever was of a mild order, the temperature lasting only three days, and in neither case reaching 103° F. at its highest. The initial fever subsided, but both children simultaneously developed an acute bronchitis, introduced by an attendant, and were febrile for a further period of three or four days. There was at the same time some enlargement of the glands under the jaw from the infected tonsils.

On Feb. 23rd, 16 days from the onset of the scarlet fever, the first patient developed hæmorrhagic purpura and was dead in 48 hours, the temperature having been normal for the previous five days and the child's general condition excellent. On March 5th, 21 days from the onset of the scarlet fever, the second patient developed hæmorrhagic purpura and was dead in three days, the temperature having been normal for the previous seven days and the child's general condition excellent.

CLINICAL AND PATHOLOGICAL NOTES.

CASE 1.—The boy, when first seen on Feb. 23rd, 16 days from the onset, was desperately ill, waxy yellow in colour, with a barely detectable pulse at the wrist, and having vomited normal stomach contents. His temperature was 98° F. There was a hæmorrhage under the skin on the left cheek and extensive hæmorrhages under the skin of both elbows, with a number of pin-point hæmorrhages over the abdomen and some more extensive hæmorrhages over the buttocks and backs of the calves. Albumin was abundant in the urine. A blood count at this time showed:—

Red cells	4,890,000	Polymorph	71 %
White cells ..	27,250	Lymphocytes ..	21 %
Platelets in large numbers.		Endothelial	8 %

Adrenalin, ♏ ii., was given four-hourly, and the pulse-rate varied between 100 and 120 during the first 24 hours, the temperature rising to 99° F. in the evening, and fluid nourishment being well taken during the day. After a restless night, with perpetual complaints of pain in the limbs, there was a rapid advance of the hæmorrhages in all areas where they were previously present; further hæmorrhages developed in the right cheek, and the left ankle-joint became distended with blood.

The waxy yellow colour of the skin of the whole body persisted throughout, contrasting vividly with the deep purple-black in the areas of the hæmorrhages. The child died during the early hours of the second night, with all the appearances of death from hæmorrhage: cold, sweating, sighing respiration, and a failing, increasingly rapid pulse. At no time was blood present in the urine, stools, or vomits; the subcutaneous hæmorrhages were, in the main, present on pressure areas. No post-mortem examination was made of this case.

CASE 2.—The girl, when first seen on March 5th, 21 days from the onset, presented a strikingly distinctive picture. Both calves, from a sharply defined and symmetrical line at the junction of the middle and upper third of the calf downwards, were deeply cyanosed, though warm, while multiple small hæmorrhages were visible in the deep blue skin on the dorsal aspect of each foot. A few pin-point hæmorrhages were also visible over the lower abdomen. Scattered over the posterior surface of the upper arm on both sides and along the outer side of each thigh were white areas of skin, varying from a threepenny-piece to a shilling in size, surrounded by an area of hyperæmia some few millimetres wide.

The temperature was normal, pulse-rate 100, and the general condition of the child good, although vomiting had occurred, as with the brother. The child was a little paler than normal, although there was at this time no sign of the waxy yellow pallor of the previous case. There was abundant albumin in the urine, although it had been absent up to the previous day, daily specimens having been tested during the preceding week. In the course of the next three hours the "blue boots" appearance entirely disappeared, as did the patches on the arms and thighs which had been surrounded by zones of hyperæmia.

Adrenalin, ♏ ii., was administered four-hourly, and liquid liver extract was given by mouth.

Immediate steps were taken to examine the blood with a view to the possibility of a transfusion. This examination revealed a most unusual condition:—

1. The patient belonged to blood group 2.
2. The patient's father was also group 2, the mother being group 4, but the patient's serum agglutinated the cells of both parents.
3. The patient's serum also agglutinated the corpuscles of her sister, who was also blood group 2.
4. The patient's serum also agglutinated the cells of five group 2 donors, and 12 group 4 donors.
5. The patient's serum agglutinated a suspension of her own red cells.

In consultation with Dr. H. Letheby Tidy, it was agreed (*a*) that blood transfusion was impossible, and (*b*) that the administration of serum, after proper precautions to avoid anaphylaxis, might be worthy relative proportion of hæmolysin to leucocidin has ever been proved. The peculiar strain, No. 5, which grows in unusually small colonies on agar (though in its general cultural properties identical with the other strains) was twice isolated from the same patient. The Group 1 strain No. 3 isolated from a carbuncle was again obtained from a stye in the same patient four months later. The association of certain classes of toxin producers with certain types of human lesions is, we think, as close as could reasonably be expected in view of the comparative crudity of our measurements and of variations in the resistance of the individuals affected, and such association supports the belief that toxin production is a constant, at any rate for the period of infection. Clinical instances also occur to us of the accidental transfer of similar staphylococcal lesions from one person to another, for example, a nursemaid with a stye transferring to a child an identical lesion or a small superficial boil.

Toxin and cell species.—A survey of the literature shows that, in estimating toxic action, the animal species from which the test cell was derived seems to have been considered a matter of indifference. Rabbit red and white cells were employed by Neisser [7] and Wechsberg, and subsequently by others, while Julianelle [3] compares the lethal action on mice or rabbits, the hæmolytic titre for horse red cells, and the leucocidal action upon guinea-pig cells. We find that toxins with a high titre for rabbit cells commonly have a lower titre for sheep cells, and may have no action upon human cells. The titre for rabbit cells often reaches 1 in 800, that for human cells rarely attains 1 in 5. Previous saturation of a toxin strongly hæmolytic for rabbit and inactive for human red cells with human cells does not reduce the rabbit cell titre. It is true that a clear zone often appears around staphylococcal colonies on human blood-agar plates, but only one of our 22 strains yielded a titre for human cells of any strength. This toxin (No. 7) gave incomplete hæmolysis throughout with a trace up to 1 in 800 and saturation of this toxin with human cells did not seem to affect the subsequent titre for rabbit red cells. It appears that human and rabbit red cell hæmolysins are distinct, and that staphylococcal toxin rarely acts upon the human red cell in vitro. The leucocidin was tested against human cells, but in some instances was tried against rabbit white cells also. It is difficult to compare these results; the human cell experiments were clear-cut, the rabbit cell results may have been prejudiced by the hæmolysis which was nearly always present, and by what appeared to be the necrosing action of the toxin imposed upon the leucocidal action. It appeared that toxin leucocidal for human cells destroyed rabbit cells also, but toxins with low titres for human cells had considerable action upon rabbit cells. There was some histological suggestion that the main effect of the latter toxins was rather upon the cell membrane than a disruptive action upon both nucleus and cytoplasm as would seem to be the case with the Group 1 toxins.

TREATMENT.

The association of certain combinations of toxins with certain types of staphylococcal infection suggests differences in the specific treatment of these conditions. We have found the employment of an antiserum to be chiefly efficacious against pyæmic infections and have already indicated our belief that the important antibody in the serum is probably the anti-leucocidin. The sycosis cases were, on the contrary, all associated with a strong hæmolysin and a weak leucocidin. These cases notoriously respond badly to vaccine treatment and are sometimes made worse by it. There is also some suggestion that they do worse with an autogenous than with a stock vaccine. In these infections the hæmolysin may be associated with the sensitising factor to which we have previously drawn attention.[8] It appears to us that treatment with toxoid in these and possibly in othe staphylococcal lesions is more rational than treat ment by vaccine, and that in the sycosis cases th toxoid should contain leucocidin and possibly th minimum amount of hæmolysin. We have treate only two such cases but both were carefully selecte as examples of extreme chronicity, widespread lesion and resistance to every form of treatment. Th result in both cases has been sufficiently encouragi to test the method further. Immunisation by tox or toxoid is, in theory, preferable to vaccine therap The vaccine dose comprises a roughly calculat number of dead bacteria, and a very uncertain amou of toxins, mixed in quite unknown proportions. T dose of toxoid can be accurately measured and a choice of toxin the relative proportions of t different constituents can be chosen at will. T comparative values of toxin and vaccine treatm can only be determined by thorough clinical tr

SUMMARY.

(1) Toxic filtrates have been prepared from strains of *Staphylococcus aureus*. Their capacity hæmolyse rabbit red cells, necrose rabbit's skin, destroy the leucocytes in human blood has b estimated. (2) The results confirm the findings others, that the hæmolysin and necrotoxin closely together with no relation to the leucoci (3) The lethal action for rabbits, when investiga was found to vary with the hæmolysin content of filtrate. (4) Comparison with the human les indicates that strains yielding strong leucocidin weak hæmolysin are commonly associated with a severe infections and the reverse combination long-standing superficial infection of the sy type. (5) Up to the present no evidence of varia in the qualitative production of toxins by the st has been obtained. (6) Suggestions as to pos lines of treatment are discussed.

LUNACY IN THE IRISH FREE STATE.—Acco to the inspection report submitted to the Gr gorman Mental Hospital committee there is a conti increase in the number of persons in the Free of unsound mind; the two institutions of Grangeg and Portrane contain 3750 patients from the count Dublin, Louth, and Wicklow. The report conti "Statistics for the Free State show that one in ever of the population is a patient of a public mental as In addition, there are a large number in private asy workhouses, and hospitals, and a large number are h away in private homes. Add to this the number of n attendants, and other officials engaged in the work of asylums, and you will approach closely to a figure of every 100 of the population not only dead to the but actually a burden to the State. A figure of one in 300 would be a more normal level." Bad housi suggested as one of the causes of mental disorder.

ontaining no excess of white blood-cells. Larger veins ended and contain a large proportion of white cells. iver.—Cellularity along Glisson's capsules.

COMMENTS.

he unusual features of the two cases here reported y perhaps be usefully enumerated.

1) Purpura hæmorrhagica as a late sequela of rlet fever appears to be extremely rare. (2) This nplication developed in two children of the same ily, 16 and 21 days respectively after an attack scarlet fever which clinically was of a mild type l unaccompanied by any evidence of unusual æmia. (3) While the mode of death was charac- istic of death from hæmorrhage, the actual loss of od evident in the one case subjected to post-mortem mination was small in comparison with the clinical emia. (4) In contrast with the case reported by x and Massingham. there was no reduction in the telets. (5) It would seem possible to conclude only that in these children there existed some unusual constitutional susceptibility to the scarlatinal toxin.

While the present paper was in preparation, Dr. F. G. Wood-Smith kindly allowed us to see the report of a similar case occurring in an adult, and with his permission the bibliography is appended.

CLINICAL AND LABORATORY NOTES

A NOTE ON
HRONIC INFECTIONS OF THE LUNGS.

BY P. JANVRIN MARETT. M.R.C.S. ENG.,
ICAL OFFICER OF HEALTH, STATES OF JERSEY, CHANNEL ISLANDS.

NUMEROUS papers have been published describing ronic infection of the lung by fungi, and the istence of streptothrix infections of the lungs is ll established as a clinical and pathological entity.[1] e weight of evidence against the view that monilia non-pathogenic to man is rapidly increasing.[2-8 10] is hardly conceivable that an organism should ert a pathogenic effect when acting alone and t be looked upon as non-pathogenic when associated th known pathogenic organisms.

Since 1922 work has been carried out in Jersey the differential diagnosis of chronic infections of e lungs. The unsatisfactory diagnosis of "closed B." led to the hope of finding an organism which ight be simulating infection with the tubercle cillus. With this in view all specimens of sputum re examined, both microscopically and culturally. The cultural examinations brought to light the esence of blastomycetes, chiefly monilias. Where. clinical grounds, tubercle had been suspected, t the bacillus had not been found, monilias were esent. Monilias were also present in tuberculous fections, and the clinical difference between the ixed infection and the rare condition of a simple berculous infection was marked, the mixed infection ing an acute condition whilst the simple one was ronic, and more resembled a carrier state.

The prevention of secondary infection with pyogenic ganisms is the key to the brilliant results obtained the modern treatment of surgical tuberculosis. he contrast between surgical and medical tubercu- sis lies in the fact that the latter, when seen by the physician, is always complicated by a pyogenic infection, chief of which are monilias. Where tubercle of the lung is a primary and single infection, it does not require treatment, and recovery is natural. This may be a somewhat startling suggestion, but the following further facts are put forward in its support.

The history of a tuberculous patient often includes an attack of a zymotic disease such as whooping-cough or measles, which has left a legacy of bronchitis or broncho-pneumonia. Many cases give a history of pleurisy, and monilias have been recovered from pleural effusions. I have known cases from which monilias have been grown out, and which within a year or so—not having been treated—have developed a secondary infection of tubercle. Chevalier Jackson,[3] using the bronchoscope, has recovered monilias direct from infected lung tissue. N. Hamilton Fairley,[7] in a discussion on a paper by Castellani, refers to the infiltration of lung tissue with gelatinous masses, in which monilia are found in large numbers.

The following Table gives the extent and the results of the work in Jersey during the four years 1927–30.

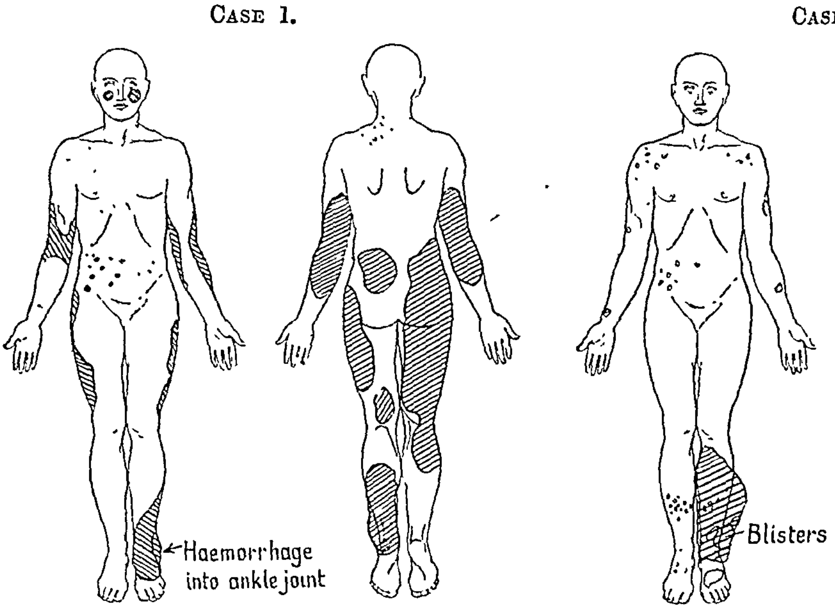
Year	1927	1928	1929	1930
Total number of patients examined ..	295	304	376	381
Number due to T.B., and blastomycetes	80	72	92	79
Number due to blastomycetes only ..	120	160	189	247
Number due to other organisms ..	95	62	94	55

Preventive treatment against infection with monilias consists in the pasteurisation of milk. Cows suffering from mastitis excrete monilias in their milk. Warts on the teats are an indication of the infection.[9]

The keynote to the treatment of chronic infections of the lungs is the removal of pyogenic organisms by drainage. Free drainage brings about improvement, with fall of temperature, clearing-up of the sputum, of consideration, and that anti-scarlatinal serum was probably the serum indicated.

During the second day the hæmorrhages rapidly developed, areas of hæmorrhage appearing on the extensor surfaces of both forearms and buttocks, while the left calf became distended with subcutaneous hæmorrhage to about twice its normal size. Late in the day it was necessary to administer morphia to relieve pain. By the evening of the second day the child was beginning to develop the waxy pallor noted in the first case. Five minims of anti-scarlatinal serum were given subcutaneously without any consequent reaction, and one hour later 5 c.cm. was administered intramuscularly.

The hæmorrhages remained constant, but intense thirst, accompanied by persistent vomiting of all fluid taken by mouth, continued during the night. Rectal salines were given and retained, but the child died during the morning of the third day, the final picture being, as in the case of the first child, death from hæmorrhage.



Distribution of purpura in the two cases.

The total amount of blood extravasated in the different lesions of the second child was small in quantity, and not in itself adequate to account for death.

POST-MORTEM INVESTIGATIONS (A. G. G.).

In Case 2 autopsy was performed 48 hours after death.

The body was moderately nourished. The greater part of the skin of both legs below the calf was purple and ecchymotic, and there were large blebs containing blood in the left leg. There were patches of purpura on the buttocks and on the extensor surfaces of both hands and wrists, and smaller petechial hæmorrhages in the upper arms. There were 2–3 c.cm. of clear fluid in the pericardium; otherwise the cavities were dry and natural. There was a local hæmorrhage in the fat of the anterior mediastinum near the pericardium.

Tonsils and lymph glands.—Both tonsils were large, pale, and on section extremely cellular, showing no crypts except one near the surface of the left tonsil which exuded mucoid, opaque fluid. There were no hæmorrhages. The neck glands below the tonsils were slightly enlarged, and on section showed the same highly cellular appearance. The tongue, pharynx, œsophagus, trachea, thyroid, and aorta were normal. The glands at the bifurcation of the trachea were small, fleshy, and dark red.

Thorax.—The heart seemed natural, with no sign of hæmorrhage; the muscle was on the pale side, but of good texture and colour. Both lungs showed moderate hypostasis, and there were a few minute petechiæ underneath the pleura. They were otherwise dry and showed no change.

Abdomen.—The mucous membrane of the stomach and intestines was normal. The liver was slightly brownish, firm, and showed the lobules under a low magnification. There were no visible hæmorrhages. The spleen was not enlarged. There was a hæmorrhage on the convex surface towards the upper pole; it had not spread for any distance into the pulp. The pulp was firm, Malpighian bodies were easily seen, and most of them had a zone of hyperæmia surrounding them. The suprarenals were thin, and the pigment layer in the lowest part of the cortex was evident. Both kidneys were pale and showed no abnormal change. The bone-marrow of the ribs was slightly paler than normal, otherwise without change. Incision into the hæmorrhage in the right leg showed that it was entirely superficial to the periosteum of the tibia, which was normal in appearance.

MICROSCOPICAL APPEARANCES.

Left tonsil.—Very highly cellular and cannot be recognised as a tonsil under the low power. Crypts that can be recognised under the high power are small cavities lined by a single layer of epithelium. The sites of other crypts probably represented by areas in which with some thelial and lymph cells there are numerous small glob bodies, possibly from nuclear necrosis. No mye *metaplasia.* The tonsillar glands show extreme lymp hyperplasia.

Right tonsil.—The crypts can be distinguished, and w the walls of some are infiltrated with lymphocytes s are normal, but none contains pus. There are several l fibrous strands in this tonsil infiltrated with lymphoc Areas of necrosis are less evident than in the left.

Spleen.—Hæmorrhage surrounds some of the Malpig bodies. Some of the sinusoids are plugged with hy clot. A section of the hæmorrhage showed the ti turgid with blood. Malpighian corpuscles s Veins have more white cells than normal. *No* hy plasia.

Thymus.—Lymphatic tissue normal. Of Hassal's puscles some are normal, some distended with epith debris. No suggestion of infection.

Bronchial gland.—Hyperplasia with patches of (?) nec as in tonsil. Hyperæmia. Increase of white cells in s vessels.

Mesenteric gland.—Hyperplasia.

Bone-marrow of ribs.—Packed with neutrophil and a eosinophil myelocytes. Normoblasts present.

Mediastinal hæmorrhage.—Some parts appear wit more than a normal number of white cells. O contain an excess. Two small vessels are packed white cells.

Skin.—The hæmorrhage here does not contain a l number of white cells (cf. the splenic and medias [illegible] on of tissue or blood-cells [illegible] om capillaries. [illegible] seen in the vessels; the arter [illegible] mal. No signs of neph A few blood-cells in glomerular capsule. Capillaries en

MEDICAL SOCIETIES

HUNTERIAN SOCIETY.

Ætiology of Chronic Bronchitis.

: the course of his Hunterian Oration, delivered ie Apothecaries' Hall to this society on Feb. 25th, J. B. Christopherson pointed out that chronic .chitis is prevalent in all walks of life. There .o commoner disorder in England, and there o more frequent, direct and indirect, cause of blement and death in the British Isles. Dr. stopherson's main thesis was that besides the ubtedly bacterial invasion of the bronchial ous membrane, there is a more fundamental e underlying chronic bronchitis, of nervous origin. frequent and intimate association with asthma, the well-established fact that asthma is anatomi- due to constriction of the bronchial muscle, first led him to think that chronic bronchitis it be caused by over-action of the sympathetic h, with the vagus, controls the bronchi. He ved the turgescence of the mucous membrane, he bronchioles of chronic bronchitis patients, e an anatomical fact of the greatest importance. turgescence was recognised by important orities as an essential part of the asthma syndrome according to Dr. Christopherson, it is probably ultimate cause of death, in the majority of ents, who die of chronic bronchitis and bronchial ma. He did not concur with the general opinion the whole pathology of chronic bronchitis is erial, and that the turgescence is inflammatory ature; in his view there exists a non-bacterial escence of chronic bronchitis, which owes its e to the action of the involuntary nervous em. There was not as yet sufficient experimental f as to whether it was produced by vagal or pathetic action. He discussed the evidence avour of regarding chronic bronchitis as (1) a erial, (2) a vasomotor disease, and proceeded to ider the clinical evidence suggesting a connexion een chronic bronchitis and the involuntary ous system, especially over-action of the sympa- ic. He pointed out that an asthmatic child itted to hospital with an acute attack of spasmodic ma will recover from his asthma in a few hours out relapsing, but the wheezing râles remain gh there is no obstruction to air entry. He rded the asthmatic attack as vagal, and the e following the attack as the reacting sympathetic ion of the vago-sympathetic complex—vascular escence and dilatation of bronchial musculature.

r. Christopherson thought that the fact that nic bronchitis frequently dates from an acute rder of the lungs might possibly find its explana- in the hypothesis that the normal vago-sympa- ic balance has been destroyed by the acute illness. fact that chronic bronchitis and asthma frequently rnate suggested a relationship of physiological nce, the vagal influence dominating at one time, the sympathetic influence dominating at another. was an interesting fact that in bronchial asthma paroxysms occur at night when sympathetic nuli are in abeyance. Chronic bronchitis was a time disease, when sympathetic influences are ongest. Another possible instance of a fluctuating siological balance was that, during the asthmatic sm the cough is hard, expectoration scanty; after spasm, when the sympathetic influences are inning to dominate, the cough is loose and expectoration increases. He believed hypertrophy of the submucous tissue to be a sympathetic phenomenon; it was the most serious part of the vago-sympathetic complex. In the cases of asthma operated on by sympathectomy, a number of successes had been reported. Spasmodic asthma being a vagal disorder, sympathectomy could only benefit by cutting out any sympathetic phenomena present. Reported successes following operation on the sympathetic nerve, in cases of asthma, might be due to the fact that the operator had attacked and relieved the sympathetic portion of the asthma complex. There appeared to be no recognisable pathological difference post mortem between chronic bronchitis and bronchial asthma. The problem of chronic bronchitis was a complicated one, and it might be that bacterial influences must also be considered, and perhaps linked up with the physiological. It was possible to link the undoubtedly inflammatory forms of bronchitis with the admitted nervous disturbance in asthma, and to account for the numerous cases, which seemed to fall between the two extremes, on the basis of bacterial allergy. If chronic bronchitis was clinically a part of the vago-sympathetic complex of asthma, asthma and bronchitis might profitably be investigated together. The success of adrenalin as a stimulant of the sympathetic nerve encouraged the hope that a rival antagonistic substance—pharmacological or biochemical, or of the acetyl-choline type—might be found to stimulate the bronchial vagus without risk.

ROYAL SOCIETY OF MEDICINE.

SECTION OF COMPARATIVE MEDICINE.

Milk Fever and Similar Conditions.

At a meeting of this section on Wednesday, Feb. 24th, Dr. J. A. Arkwright, F.R.S., the President, being in the chair, a discussion took place on Milk Fever in Parturient Cows and Similar Conditions in Other Animals and the Human.

Prof. J. Russell Greig, in opening, said that the pathology of the condition known as milk fever in cows, like that of eclampsia in women, to which it bore a clinical resemblance, had long been obscure. In most instances it attacked cows within 72 hours after calving, the parturition itself having been uneventful. The onset of the milk fever was usually abrupt; the first symptom was excitement, and this was followed by tetany, which might be confined to the hind limbs, or might involve all four limbs. Convulsive seizures, when they occurred, rapidly led to coma. In 1897 Schmidt discovered that the injection of fluid into the mamma produced prompt and complete cure. This injection method was later replaced by inflation of the breast. These measures had reduced mortality from between 60 per cent. and 70 per cent. to less than 1 per cent.—a remarkable result. It was not clear how mammary inflation produced the cure. In 1924 jointly with Prof. H. Dryerre, Prof. Greig had formulated a working hypothesis in which it was suggested that the essential condition was a parathyroid deficiency with a fall in the blood calcium, the latter deficiency being accentuated by lactation. The colostrum of the cow revealed a very high concentration of calcium. Mammary inflation produced, he submitted, a stimulation of adrenal secretion, and consequently increased the excretion of any toxins which might be present;

and increase in weight. Any recurrence of symptoms is found to be due to a relapse of the monilia infection. Pneumothorax and aspiration by the bronchoscope are simply surgical methods of drainage, but such treatment is applicable to gross lesions. Medical treatment requires the institution of medical drainage at the earliest possible moment. When sputum is tenacious, there can be no free flow of secretion. When a thick purulent or gelatinous sputum is present, culture will usually reveal the presence of monilias, and on the finding of monilias, medical drainage must be commenced.

Alkaline potassium iodide is the drug for the purpose; it acts in the following ways: (*a*) sputum is liquefied; (*b*) a free flow of secretion is set up from within outwards, thus preventing the ingress of organisms; and (*c*) the drug has a selective action on fungi. It has been stated that iodides tend to decalcify the body. What effect has chronic suppuration on the calcium content of the body? If iodides do decalcify, then the answer is: replace the calcium loss by the exhibition of a calcium salt.

Vaccines are used to increase immunity against monilia. The vaccine is used in two forms. A first course consists of monilia grown on agar; this only contains the yeast form. When monilia persists after a first course, a second course is given where the monilia is grown on Sabouraud; the vaccine thus grown contains all elements of monilia, including mycelium. Tubercle vaccine is only used when the patient is apyretic. If acute symptoms return a cultural examination of the sputum is made, and if monilia is found, the patient reverts to monilia vaccine.

RUPTURE OF AN ANEURYSM OF THE ABDOMINAL AORTA.

BY J. H. PEEL, B.M. OXF.,

HOUSE SURGEON TO THE UROLOGICAL DEPARTMENT, KING'S COLLEGE HOSPITAL, LONDON.

A WOMAN, aged 68, admitted to King's College Hospital, said she had suffered for a number of years from what she called rheumatism. But the illness which brought her into hospital started only three weeks prior to admission, before which she had been comparatively healthy.

She complained of pain in the right lumbar region. It was never very acute, but a dull heavy ache, localised in the right loin. She began to feel very ill, complaining of nausea and loss of appetite at first, and later she began to vomit. For a few days before admission she had been unable to keep any food down at all. She felt very thirsty but she vomited even water. Hiccup started three days previously, and had been persistent up to the time of admission. She had gradually become more drowsy and apathetic. The bowels had been very constipated; hæmaturia, which had been noticed for a week, had persisted, but there had been no frequency or pain on micturition. The illness had started with a febrile attack, and the temperature had remained elevated for the whole three weeks prior to admission. Before the hæmaturia started there was no albumin or pus in the urine.

When the patient was first seen, she presented a typical picture of uræmia. She was very drowsy, could only be roused with difficulty, and talked incoherently. The tongue was red and very dry. There was persistent hiccup and the patient kept retching and vomiting. She was parched with thirst. The temperature was 100·6°, the pulse-rate 100, and the respiration-rate 22. The pulse was poor in volume, although the blood pressure was 160/90. There was slight twitching of the left eye; the discs were normal On examination of the abdomen there was found to be a large firm tumour in the region of the left kidney. The swelling was tense and very tender, but was not absolutely fixed. There was a transmitted pulsation.

Examination of a catheter specimen of urine showed the presence of a number of red blood-cells and pus cells. There were no casts, crystals, or epithelial cells seen, and no organisms in direct smears. The culture was proved subsequently to be sterile. The blood-urea was found to be 217 mg. per 100 c.cm.

The diagnosis of a renal tumour causing uræmia seemed reasonable, and the patient was treated accordingly. She was given one pint of saline with 5 per cent. glucose subcutaneously, and this wa given again intravenously six hours later. She wa given purgatives and diuretics as well. For severa hours the general condition improved considerably the vomiting almost stopped, and the patient was les drowsy and more coherent. Quite suddenly abou 12 hours after admission she collapsed and died.

Post-mortem revealed an astonishing and une pected condition. On opening the peritoneal cavit it was found to contain nearly two pints of free bloo The tumour in the kidney region was an enormou perinephric hæmatoma, about the size of a melo completely enveloping a small arterio-sclerotic kidne The right kidney was also a small arterio-sclerotic on This was apparently the explanation of the rais blood pressure and the undoubted uræmia. T whole of the aorta (thoracic and abdominal) show marked syphilitic scarring. There was a rupture the aorta about 1½ in. above the bifurcation the aorta on the left side, communicating with aneurysmal sac the size of an orange. Leakage fr this had caused the perinephric hæmatoma, a further rupture of this into the peritoneum h caused the terminal hæmorrhage, from which t patient died suddenly. The aortic valves show early syphilitic lesions. There was a gumma in t liver adjacent to the gall-bladder and adherent the second part of the duodenum.

This case is recorded by kind permission of J. Everidge.

WEST SUSSEX CONTRIBUTORY FUND.—Five yea working of this scheme has resulted in a members of approximately 17,800, and during this period sum of £16,461 19*s.* 8*d.* has been paid to the ass ated hospitals for treatment of members; 853 memb or their dependents, benefited as in-patients, and 1447 out-patients. Of these, 757 and 1407 respectively w treated in associated hospitals, the remainder going other hospitals in Sussex. These figures are exclusive children of members treated under the county council tonsils and adenoids, and dental treatment paid for by fund. While the committee is satisfied with the ste progression of the fund—there was an increase of just c £400 in income during 1931—it is pointed out in the annual report "that in some outlying districts served the smaller associated hospitals, the idea is still preva that the fund belongs to the Royal West Sussex Hospi and that local prople do not realise that their own hosp is just as much a part of the fund as the larger one." suggestion is made that if all the associated hospitals t individual steps to identify themselves with the fund in t own localities, this false impression would soon be remov and result in an immediate increase of membership. A v satisfactory feature of the working of the fund during 1 was the complete liquidation of a suspense account wh was opened at a bank to finance the formation of the fu atical. was closely allied to the eclampsia found nen. In women the toxæmias of pregnancy d chiefly in strong and well-developed multi- in cows also the disease occurred mostly in good milkers. not in the first pregnancies, er two or three calves had been born. In cows yielded 30 to 35 litres of milk a day the whole ontent of the animal was no more than 45 litres. had been suggested that in these cows the blood too concentrated. When thinking of the us quantity of milk excreted, it was easy to how much blood must pass from the liver e systemic blood; in eclampsia. he believed, was too great a rush of blood through the ry paths of the liver. causing a poisoning general system. Prof. Greig had said he did d a rise in the blood pressure after carrying flation of the mamma. But if one occluded capillary area. a rise of blood pressure must and if this was not evident. it must mean that was an increased flow through some other eral part. After mammary inflation there was excretion and a diminished flow through the system; the systemic blood became purified, t the animal got well. As to the way in which n acted, it had been shown that carbon loride poisoning in dogs could be prevented rior administration of calcium; Prof. Browne t that the only way the calcium could act y stimulating the hepatic cells. Lack of n resulted in paralysis of tissue cells. so depleting iciency of the liver cells which were stimulated cium therapy.

. F. W. **Wooldridge** said he had often seen len restoration of consciousness in cows as a of inflation of the udder in milk fever: the nce produced in twenty minutes was very sive. If the condition was one of hypo- mia. it was difficult to understand how inflation udder could influence it. In his view hypo- mia was one of the effects of the disease known lk fever, not the cause. If that was so, Prof. e's theory as to the action of calcium on the ells fell to the ground as an explanation of the n recoveries after inflation. He did not think ause of the condition had yet been found. tly he saw a milch goat which had been a very milker. Five months previously a kid had born to it. It was fatigued after a long railway y. refused its food. and the milk fell off almost . After three days it showed all the symptoms ied as typical of milk fever. He decided to der inflation empirically: within fifteen minutes at. from being apparently dead, raised its head, cabbage. and a few minutes later was standing r feet. His own suggestion was that the disease neurosis of some kind. though he had no theory how it was produced.

SECTION OF ORTHOPÆDICS.

a meeting of this section. held on March 1st. hair was taken by the President. Mr. **Harry** r, and a discussion on

Fractures Round the Ankle-joint

opened by Mr. R. **Broomhead**. He classified ure dislocations of the ankle-joint into adduction abduction fractures. Both were, he said. due ndirect violence. the former to torsion and the r to simple leverage. There were three degrees e abduction type: (1) when the internal lateral nent was intact: (2) when the ligament was torn or the malleolus fractured: and (3) when. in addition. the astragalus was misplaced or the posterior margin of the tibia was fractured. The third degree type proved difficult to reduce, and restoration of function was hard. Treatment depended on the displacement. Those without displacement did not require immobilisation. Walking might be commenced early. with a firm though mobile support. When there was displacement. reduction was easy if it was possible at all; the others usually required open operation. Inversion should be obtained by inverting the back-foot and not by twisting the fore-foot. Adduction fractures were much more unstable. and should be fixed at a right angle. One of the best-known and most widely used methods of ambulatory treatment was Delbet's. Patients could walk about quite well if a special shoe were fitted over the plaster. Other forms of treatment included Böhler's. which was one of the most practical, although he did not allow walking until all swelling had subsided. Plaster was ideal as a protective splint. but not so useful as a corrective. and fractures with displacement were better treated in bed. There was no evidence that return to work was possible any earlier after the plaster methods.

Operation was to be advised in some third degree abduction fractures. some second degree adduction fractures. and all compound fractures. The skin of the foot had great potentialities for sepsis. and operation should be delayed until the skin had been prepared and the swelling had subsided. In adduction fractures the internal malleolus and in abduction fractures the external malleolus must be fixed. and often the posterior tibial margin as well. One alternative was to fuse the ankle-joint after all swelling had subsided—in about a fortnight; the other was to do all that could be done by conservative treatment at first. and then to fuse the joint in six months' time if function was inadequate. Vaseline pack dressings had proved very satisfactory for compound fractures. Amputation was often worth consideration as an immediate measure. as it saved a long and painful period of treatment with a useless joint as the result. It was very important—and often difficult—to get early and complete reduction in cases of separated epiphysis.

General anæsthesia was preferable; local anæsthetics had proved disappointing. Some 20 c.cm. of fluid had to be introduced into an already swollen limb. and often spasm of the peroneal muscles was not abolished by the injection, so that the displacement recurred as soon as the hands were removed. These fractures had great importance in relation to compensation claims. Return to work should be possible in eight to ten weeks. If there was displacement with marginal fracture the patient was usually disabled for 16 to 18 weeks, and often up to six months.

FRACTURES OF THE ASTRAGALUS.

Mr. J. P. **Hosford** said that he had only found 15 cases (in 13 patients) of fracture of the astragalus at St. Bartholomew's Hospital in the last ten years. The neck was the part most commonly broken, and the ankle-joint might or might not be involved. The cause was seldom a direct blow as the astragalus was so well protected, and in twisting strains the malleoli fractured more easily than the astragalus. The most usual history (in nine cases) was a fall on to the heel from a height. and often there was some other gross lesion in the tarsus or a subastragaloid dislocation. There were four types: *fractures of the neck*: fractures of the posterior process; crush-

or it caused a reduction of the milk secretion and a further transference of calcium from the blood to the milk. The curative effect of inflammation of the mamma was due to the restoration to that organ of its due blood calcium. Once an animal had been attacked by this malady there were likely to be recurrences at the subsequent calvings. In every case of milk fever investigated the blood calcium was deficient. Moreover the progress of cure, as manifested in the disappearance of symptoms, corresponded with the rise in the blood calcium, which remained abnormally high for five days. As would be expected, the injection of calcium salts cured the condition. The recovery of the cow from its torpor and helplessness after treatment was dramatic; very definite improvement was noted in five minutes, the change being especially rapid when the injection was intravenous.

The calcium deficiency might have its basis in a parathyroid deficiency, or there might be a great loss of calcium in the milk. There was as much calcium in half a gallon of colostrum as in the whole of the soft tissues of the body. Possibly mammary distension cured the disease by preventing a further transference of calcium from the blood to the milk. In ewes there occurred a "lambing sickness" which was much akin to the condition just mentioned. Investigation of a series of cases showed the following blood calcium contents:—

		Normals.	Lambing sickness.
mg. per 100 c.cm. of serum.	Maximum ..	11·92	5·94
	Minimum ..	7·92	3·51
	Average ..	9·80	4·10

These figures were confirmed in an investigation by Sjollema. Mares suffered from a similar disease, and they responded with equal suddenness to mammary inflation or injection of calcium salts; the same was true of the parturient goat, sow, and bitch.

As milk fever appeared to represent a metabolic upset and seemed to occur in all domesticated animals, it was reasonable to assume that a similar condition occurred in woman, and there were parallel symptoms in eclampsia. The blood condition in the two was, however, markedly dissimilar. In serious cases of eclampsia inflation of the breasts gave no response, and the results of calcium injections in this disease had not been encouraging. Yet a case of eclampsia recorded in 1931 by Dr. J. G. Kinnimonth suggested that a condition which was pathologically related to milk fever in domestic animals did occur in the human; the symptoms here closely resembled those of milk fever in the cow, and prompt and complete recovery followed inflation of the breasts. There was also some parallelism between eclampsia and a disease in ewes known as pregnancy toxæmia.

Prof. DRYERRE, who had been investigating ewes, said that the ewe was sometimes affected before the lamb was born. He was convinced that many cases of pregnancy toxæmia in ewes were confused with those of lambing sickness. Some writers had had no success with calcium injections in lambing sickness, but Prof. Dryerre suggested that their cases were really those of pregnancy toxæmia. Some confusion was natural, since in both conditions the animal was unsteady of gait, and liable to fall, and might be almost comatose. Calcium salts had no effect in the toxæmia of pregnancy—indeed, their injection might hasten the fatal termination. In an investigated series there was no significant difference in the blood calcium or the potassium content; between the normal animal and the animal suffering from pregnancy toxæmia; the magnesium showed a slight difference, and the inorganic phosphorus in pregnancy toxæmia was lower than the normal. There was a fall of blood calcium in eclamptic cases, but not to a significant extent, and it was thus not likely to be a causal factor.

Prof. E. C. DODDS referred to an investigation he had conducted into tetany as manifested in some Welsh mountain ponies, which had been captured on the hills and transferred in railway trucks. These animals developed an illness bearing a clinical resemblance to milk fever; their blood calcium was low and restoration followed the giving of calcium intravenously or subcutaneously. In these animals there was no calcium loss to account for the low bloo calcium; his view was that the fright induced b their capture and the railway journey induced a alkalosis. If so, there was no need to postulate loss of calcium in the milk. He considered that an attempt to establish a parallelism between the mi fever of cows and eclampsia in the human was doom to failure. While in milk fever the blood calcium w said to be always low, in eclampsia the blood calciu might or might not be low, bile pigment might in the blood, or the blood-urea might be high. T other great difference between milk fever and eclamps was in the blood pressure. The latter provided t best indication to the prognosis in a case of eclamps Apparently in the cow the blood pressure was n high after inflation of the udder. From a search the literature, he had come to the conclusion that t only condition comparable in women to milk dise in cows was lactation tetany, which was sometin found in women who prolonged lactation nine months, or over. He asked whether alkalo was considered a reasonable explanation of symptoms in domestic animals; it seemed to easily excited.

Mr. W. L. LITTLE said he had had experience milk fever in the cow, the goat, and the dog, and able to trace a number of disabilities following u insufficient diets. The cow needed much lime. felt sure that an excess of phosphates interfered w the assimilation of the calcium, and in this cour the diet of most cows was fairly rich in phospha As milk fever was prevalent on some farms very rare on others, he suggested that the ex phosphorus taken might interfere with the calc assimilation. The best results had followed wi feeding on a combination of cod-liver oil and calc salts. Injection of calcium salts just after cal prevented the onset of the disease on farms wl it was prevalent. Autopsies on a number of c of milk fever showed that in most of the cases the de was from septic pneumonia. In deaths occur after very severe attacks there were changes in muscles, the affected muscles showing a dry nec and blood extravasation between the fibres. In kidneys and bladder small hæmorrhages were evid He advised that calcium injections should be gi very slowly.

Mr. O. STINSON spoke of his experiences with ca on two farms in Westmorland very dissimila the matter of soil. In one the cattle showe distinct aphosphorosis; if the animals were tr ferred to the other farm for a time these sympt disappeared.

Prof. F. J. BROWNE did not feel able to acc Prof. Greig's explanation of interpretation. Tho there might be hypoglycæmia in the blood of t animals, he did not think the essential pathol of the disease was due to that. What was the c of the deficiency in the function of the parathy gland? He thought the condition in cows, though ntical, was closely allied to the eclampsia found women. In women the toxæmias of pregnancy urred chiefly in strong and well-developed multi- æ; in cows also the disease occurred mostly in ong good milkers, not in the first pregnancies, t after two or three calves had been born. In cows ich yielded 30 to 35 litres of milk a day the whole od content of the animal was no more than 45 litres, d it had been suggested that in these cows the blood ame too concentrated. When thinking of the ormous quantity of milk excreted, it was easy to ture how much blood must pass from the liver o the systemic blood; in eclampsia, he believed, re was too great a rush of blood through the illary paths of the liver, causing a poisoning the general system. Prof. Greig had said he did t find a rise in the blood pressure after carrying t inflation of the mamma. But if one occluded arge capillary area, a rise of blood pressure must sue, and if this was not evident, it must mean that re was an increased flow through some other ripheral part. After mammary inflation there was ater excretion and a diminished flow through the rtal system; the systemic blood became purified, that the animal got well. As to the way in which cium acted, it had been shown that carbon rachloride poisoning in dogs could be prevented a prior administration of calcium; Prof. Browne ought that the only way the calcium could act s by stimulating the hepatic cells. Lack of cium resulted in paralysis of tissue cells, so depleting e efficiency of the liver cells which were stimulated calcium therapy.

Prof. F. W. WOOLDRIDGE said he had often seen sudden restoration of consciousness in cows as a ult of inflation of the udder in milk fever; the ference produced in twenty minutes was very pressive. If the condition was one of hypo- cæmia, it was difficult to understand how inflation the udder could influence it. In his view hypo- cæmia was one of the effects of the disease known milk fever, not the cause. If that was so, Prof. owne's theory as to the action of calcium on the er cells fell to the ground as an explanation of the dden recoveries after inflation. He did not think e cause of the condition had yet been found. ecently he saw a milch goat which had been a very avy milker. Five months previously a kid had en born to it. It was fatigued after a long railway urney, refused its food, and the milk fell off almost nil. After three days it showed all the symptoms garded as typical of milk fever. He decided to udder inflation empirically; within fifteen minutes e goat, from being apparently dead, raised its head, ok cabbage, and a few minutes later was standing her feet. His own suggestion was that the disease as a neurosis of some kind, though he had no theory to how it was produced.

SECTION OF ORTHOPÆDICS.

AT a meeting of this section, held on March 1st, e chair was taken by the President, Mr. HARRY LATT, and a discussion on

Fractures Round the Ankle-joint

as opened by Mr. R. BROOMHEAD. He classified racture dislocations of the ankle-joint into adduction nd abduction fractures. Both were, he said, due o indirect violence, the former to torsion and the atter to simple leverage. There were three degrees f the abduction type: (1) when the internal lateral igament was intact; (2) when the ligament was torn or the malleolus fractured; and (3) when, in addition, the astragalus was misplaced or the posterior margin of the tibia was fractured. The third degree type proved difficult to reduce, and restoration of function was hard. Treatment depended on the displacement. Those without displacement did not require immobilisation. Walking might be commenced early, with a firm though mobile support. When there was displacement, reduction was easy if it was possible at all; the others usually required open operation. Inversion should be obtained by inverting the back-foot and not by twisting the fore-foot. Adduction fractures were much more unstable, and should be fixed at a right angle. One of the best-known and most widely used methods of ambulatory treatment was Delbet's. Patients could walk about quite well if a special shoe were fitted over the plaster. Other forms of treatment included Bohler's, which was one of the most practical, although he did not allow walking until all swelling had subsided. Plaster was ideal as a protective splint, but not so useful as a corrective, and fractures with displacement were better treated in bed. There was no evidence that return to work was possible any earlier after the plaster methods.

Operation was to be advised in some third degree abduction fractures, some second degree adduction fractures, and all compound fractures. The skin of the foot had great potentialities for sepsis, and operation should be delayed until the skin had been prepared and the swelling had subsided. In adduction fractures the internal malleolus and in abduction fractures the external malleolus must be fixed, and often the posterior tibial margin as well. One alternative was to fuse the ankle-joint after all swelling had subsided—in about a fortnight; the other was to do all that could be done by conservative treatment at first, and then to fuse the joint in six months' time if function was inadequate. Vaseline pack dressings had proved very satisfactory for compound fractures. Amputation was often worth consideration as an immediate measure, as it saved a long and painful period of treatment with a useless joint as the result. It was very important—and often difficult—to get early and complete reduction in cases of separated epiphysis.

General anæsthesia was preferable; local anæsthetics had proved disappointing. Some 20 c.cm. of fluid had to be introduced into an already swollen limb, and often spasm of the peroneal muscles was not abolished by the injection, so that the displacement recurred as soon as the hands were removed. These fractures had great importance in relation to compensation claims. Return to work should be possible in eight to ten weeks. If there was displacement with marginal fracture the patient was usually disabled for 16 to 18 weeks, and often up to six months.

FRACTURES OF THE ASTRAGALUS.

Mr. J. P. HOSFORD said that he had only found 15 cases (in 13 patients) of fracture of the astragalus at St. Bartholomew's Hospital in the last ten years. The neck was the part most commonly broken, and the ankle-joint might or might not be involved. The cause was seldom a direct blow as the astragalus was so well protected, and in twisting strains the malleoli fractured more easily than the astragalus. The most usual history (in nine cases) was a fall on to the heel from a height, and often there was some other gross lesion in the tarsus or a subastragaloid dislocation. There were four types: fractures of the neck; fractures of the posterior process; crush-

or it caused a reduction of the milk secretion and a further transference of calcium from the blood to the milk. The curative effect of inflammation of the mamma was due to the restoration to that organ of its due blood calcium. Once an animal had been attacked by this malady there were likely to be recurrences at the subsequent calvings. In every case of milk fever investigated the blood calcium was deficient. He thought the condition in cows, though

REVIEWS AND NOTICES OF BOOKS

htheria, Past and Present.

ts Ætiology, Distribution, Transmission. and revention. By J. Graham Forbes, M.D., R.C.P., D.P.H., Principal Assistant Medical fficer, London County Council. With an intro- uctory note by Sir Frederick Andrewes, M.D., R.S. London : John Bale, Sons and Danielsson, td. 1932. Pp. 832. 45*s*.

r. Graham Forbes presents in this volume of some pages what is probably the most comprehensive unt of diphtheria, considered from the public lth and preventive aspects, which has ever been mpted. As regards prevention, at least, it is ost literally accurate to say that the survey ends from China to Peru. The last publication diphtheria comparable in importance with the sent work was the monograph by several authors, ed by the Medical Research Council in 1923. that monograph diphtheria was discussed chiefly n the bacteriological and pathological aspects, ough the methods of specific prevention then ilable were brought under review ; the last few rs have seen diphtheria added definitely to the of preventable diseases. Dr. Graham Forbes ides his book, which is founded upon his Milroy ures of 1929, into four sections dealing respectively h ætiology, distribution, transmission, and pre- tion. Each section is abundantly furnished with ps, charts, and statistical tables which add to the ue and clearness of the text. The section on vention occupies about half the book, and rightly since it is by far the most important.

he first three sections present a very complete ture of the natural history of diphtheria in England Wales. The incidence of the disease in the nties and large cities is discussed in detail and ealth of epidemiological data is supplied. These tions form a background, which, it is to be hoped, y come to be chiefly a historical background to section on prevention. Here the first steps the displacement of diphtheria as one of the lemic lethal diseases of childhood are described, l the measure of achievement is recorded, country country, county by county, and town by town. t is satisfactory to learn the extent to which ive immunisation has already been adopted in s country. As one of the most tireless apostles the specific prevention of diphtheria, Dr. Graham rbes must have been gratified to observe the rease in the numbers of children protected since publication of his Special Report to the Medical search Council No. 115 in 1927. Active immunisa- n has now at least been commenced in a large mber of towns, great and small, in England and les. Scotland, and particularly Edinburgh, early lised the advantages of a child population immune diphtheria. France and America are well ahead us *in this matter* ; in those countries active immuni- ion against diphtheria has been adopted with mething more than tolerance and in some towns the United States even with enthusiasm. Though hick's test for immunity is acknowledged by all mpetent observers to be valid, its performance by no means essential as a preliminary step. The nission of the initial test merely results in the immunisation " of a few children already immune, d since the measures adopted are simple and can no harm, this does not matter. Indeed, since with the extension of the practice of immunisation some of the work must inevitably be carried out by practitioners with little experience of the test, the omission may be wise, and it has the further advantage of reducing the number of attendances of the mother and child. Active immunisation by the injection of one of the preparations described by Dr. Graham Forbes may be started at the first visit. The second injection follows, preferably, three weeks later, and the third and last a fortnight after that. A confirmatory Schick test is desirable when possible after attempted immunisation.

The preparations now used in this country are said to be devoid of risk. Reactions, whether local or general, are rare, and there is no negative phase. Toxoid (Glenny), the anatoxine of Ramon, is diphtheria toxin which has been digested with formaldehyde. The resulting product, whilst completely non-toxic, retains unimpaired its power of stimulating the production of antitoxin. Toxoid, with or without antitoxin, in soluble or in floccular form, has completely replaced, in Great Britain and France at least, the old toxin-antitoxin mixtures. Dr. Graham Forbes supplies ample evidence of the results of active immunisation against diphtheria. Whether it is applied to specially exposed adults, such as nurses in fever hospitals, or to children in orphanages or homes, school-children or children below school age, the reports are the same. Whenever the measure has been introduced upon a sufficient scale there has been a notable diminution in the incidence of diphtheria.

The task which Dr. Graham Forbes set himself was onerous. He has performed it with conspicuous ability and faithfulness and his work is an important addition to the literature of preventive medicine. The labour involved in the collection and analysis of the facts compels admiration. No public health department should fail to add this volume to its books of reference, and it is to be hoped that members of public health committees, if they do not purchase, will at least borrow it.

A Manual of Surgery.

By Alexander Miles, M.D., LL.D., F.R.C.S. Edin., Consulting Surgeon, Royal Infirmary, Edinburgh ; and D. P. D. Wilkie, F.R.C.S. Edin. and Eng., Professor of Surgery, University of Edinburgh. Vols. II. and III. London : Humphrey Milford, Oxford University Press. 1932. Pp. 685 and 578. 12*s*. 6*d*. each volume.

These two volumes complete the new Thomson and Miles surgery, now under the combined authorship of Mr. Miles and Prof. Wilkie. We have little to add to our review of the first volume. Seen as a whole, it is a very satisfactory work from many points of view. The authors are adepts at providing just the amount and kind of knowledge the average undergraduate wants. They have shown judgment both in the selections and rejections, and the presentation of material is singularly free from bias. The volumes are of convenient size, not too heavy to hold in the hand, and the print is easy to read, whilst the numerous illustrations must materially assist the student's understanding of surgery. A pass examination should have no terrors for a candidate who knows his Thomson and Miles, and he will have fractures of the body, and chip fractures. Pain might be caused by bony block due to displaced fragments. In a severe case the symptoms resembled those of a Pott's fracture; the hollows on either side of the tendo Achillis might be filled if there had been backward displacement. Some cases could only be diagnosed radiographically. The treatment was immobilisation in a plaster cast and rest for eight to ten weeks. If the head was displaced medially it must be manipulated into position before the plaster was applied. Reduction of a posteriorly-displaced fragment might need open operation. The function in unreduced cases was very bad. Fractures of the body were generally irregularly comminuted, and each case must be judged on its merits. If there was bony block the fragment must be removed. Any sub-astragaloid dislocation must be reduced. Amputation was necessary in open fractures where the astragalus was pulped. Operation was required in about half the cases, and there was in most cases some permanent disability of the ankle.

SEPARATED TIBIAL EPIPHYSIS AND CHRONIC ARTHRITIS.

Mr. E. P. **Brockman** described a new method of treating those cases in which growth of the tibia had ceased after separation of the epiphysis but growth of the fibula had continued, distorting the foot. He did an osteotomy of the tibia, plugging it with the growing end of the fibula, which he removed. Since growth in the tibia had ceased, there seemed no harm in stopping growth of the fibula, and the results had been satisfactory.

If a case of old Pott's fracture developed constant pain in the ankle, operation was indicated, and there was no reason for delay. Mr. Brockman advocated arthrodesis, and described his method for these cases, mentioning good results in 12 cases.

DISCUSSION.

The **President** described a survey he had made of ankle-joint fractures at the Ancoats Hospital in the decade 1920–30. The treatment had responded to the dictates of surgical fashion. In the first four years the handling had been *conservative: manipulation*, plaster fixation, and very late weight-bearing. The ultimate industrial results had been satisfactory. For the next three years the Delbet plaster had been used both as an ambulatory splint and as the primary method of fixation, early weight-bearing being encouraged. With earlier weight-bearing there had undoubtedly been earlier return to work. During the last two or three years the Delbet plaster had been given up on the grounds of expense, and Böhler's skin-tight complete plaster had been used, and the patient allowed to walk early, either on a stirrup or on a slab of plaster. The Delbet method could be very successful as a method of primary fixation. Prompt reduction could be *followed by perfect restoration*, and there was little tendency to redisplacement. Mr. Platt saw no place for primary open operation.

Mr. G. **Perkins** preferred *Ashurst's classification* of these fractures in ætiological groups: (1) External rotation, causing fracture of the internal malleolus and a spiral fracture of the lower end of the fibula, often with backward dislocation of the foot. This was easy to reduce and no disability followed. (2) Abduction, due to an abducting force on the foot, causing a high transverse fracture of the fibula, and breaking off the internal malleolus—rather difficult to reduce and very apt to recur. (3) Adduction—not very common, difficult to reduce, and often needing operation. (4) T-shaped into the joint, due to a vertical force passing up the leg. Each type required different treatment and offered a different prognosis.

Mr. N. L. **Capener** mentioned a late result of fracture of the astragalus: compression changes, *presumably due to interference* with the blood-supply, followed by sclerosis and compression.

Mr. **Dudley Buxton** thought that fracture of the lower end of the fibula with no displacement whatever was by far the commonest type. It required support for six or eight weeks. He suggested that ambulatory treatment had become popular at a time when every hospital was experiencing pressure on its beds. Immediate reduction was of the first importance, followed by fixation in an apparatus to keep the fracture reduced. The advantage of the stirrup, or a good thick plaster support, was that i enabled patients to walk without crutches. He kep plaster on for eight weeks in cases which had bee perfectly reduced, and a week or two longer if ther had been a slight error in reduction. Some fee would swell however they were treated; and Elastc *plast bandage was useful if swelling* persisted.

Mr. **Roberts** advocated the Delbet plaster for it simplicity, its allowance of early dorsiflexion and earl *ambulatory treatment without crutches*, its comfor its self-massaging action, and the absence of swellin It must, he said, fit the patient very accurately, bei moulded to the whole limb, including the mallec and the external peroneal nerve. There was le tendency to osteo-arthritis if the patient got abo early. A fracture was in a good position if t astragalo-tibial line was horizontal. The use of needle for local anæsthesia made a fracture compoun

Mr. **Naughton Dunn** said that reduction a prolonged fixation were the secret of the treatme of all fractures. He had never plated any fractu Most speakers had advocated too brief a period fixation. The result depended partly on the type patient; he agreed that arthrodesis offered the b course if pain persisted.

Mr. **Rowley Bristow** supported Ashurst's cla fication, and agreed that for the first type compl and early reduction was absolutely essential. long as the fracture was reduced, the subsequ treatment did not matter. Anæsthesia should alw be general. In the second type the difficulty reduction was nothing to the difficulty of keep the fracture reduced. This type required prolon fixation, followed by raising of the heels, an outs iron, and a T-strap. The difference between pr nosis and treatment in the two types illustrated value of the classification.

Mr. **Broomhead** replied.

Children's Ward at Beckenham Hospital. Sir George Sutton last week opened the children's w which, at a cost of £6000, he has presented to Beckenl Hospital. Instead of four cots in the adult wards t are now 12 cots and beds. The addition has been na the "Ruth Sutton Ward" in memory of the late L Sutton.

"Law Touts" in Hospitals.—The attent of hospital managers has been called by the Incorpor Law Society to the frequency with which "touts" certain solicitors visit accident patients in hospitals endeavour to persuade them to sue for damages. practice is to suggest that if the case is placed in hands of the "tout" he will do the work free of charg the event of failure, and will charge only two shilling the pound when damages are obtained. Should, howe the damages be substantial the solicitor's remuneratio likely to be much larger than the costs he could prop charge.

MILK AND VITAMINS

MILK IS RECOGNISED AS A PERFECT FOOD, AND CADBURYS MILK CHOCOLATE CONTAINS 1½ GLASSES OF MILK IN EVERY ½ LB. BLOCK. THE SPECIAL PROCESS USED ENSURES A LARGE PERCENTAGE OF THE VITAMINS A, B AND D, PRESENT.

gone very far towards reaching the standard required in the higher surgical diplomas and degrees. One small criticism suggests itself. Whilst the illustrations serve their purpose of demonstration fairly consistently, they nearly all seem to be half-tone blocks reproduced from photographs and are not nearly so attractive as the drawings which were common in the older editions. Moreover, some of the old illustrations seem to have been photographed and to have rather lost value in the reproduction. In all other respects the authors deserve congratulations on having completed their task of revision in an eminently satisfactory manner.

Die Dickdarmschleimhaut, Ihre Normale und Pathologische Funktion im Roentgenbilde.

By Priv.-Doz. Dr. WERNER KNOTHE, Head of the Radiological Department of the II. Medizinischen Universitats-Klinik der Charité, Berlin. Leipzig: Georg Thieme. 1932. Pp. 56. M.8.

THIS small volume on the changes in the mucous membrane picture of the large intestine follows closely on the work recently published by Albrecht on the mucous membrane of the stomach. Both are inspired by Hans Berg, who followed up the pioneer work of Forssell and brought it into every day use. Dr. Knothe has recorded here his observations on the mucous membrane of the large intestine. His study is beautifully illustrated by many radiograms of a high standard, which show clearly the different forms and varieties of mucous membrane as seen in relief picture. It is a good piece of work, but the author does not always convince us (except in regard to certain well-recognised conditions) that the appearances shown are necessarily produced by the pathological or disordered physiology to which they are ascribed—e.g., we do not know that it is "irritation" that produces certain changes in the relief picture. It is a moot point whether a pathologist would recognise "irritation" of the mucous membrane except when it is severe enough to cause some degree of inflammation. Opportunities for control are rare. The proof of cause and effect sometimes appears to be slender, especially when we consider the extraordinary variations of the normal that must be possible in such a mobile structure as the living mucous membrane. It seems possible that Dr. Knothe may have gone too far in the interpretation of his shadow pictures. In spite of the obvious difficulties, work of this kind should be pursued for a long time on subjects who may be presumed to be normal. It is only by the study of normal physiology that relatively slight changes in the relief picture of the mucous membrane can be interpreted correctly and deductions on disordered physiology made.

The get up and standard of reproduction of this book are very satisfactory, as in fact are all the radiological books that we have seen coming from this publishing house.

Abnormal Psychology.

By H. L. HOLLINGWORTH, Ph.D., Professor of Psychology, Barnard College, Columbia University. London: Methuen and Co., Ltd. 1931. Pp. 556. 15s.

Prof. Hollingworth has attempted, with a considerable measure of success, to cover the whole field of psychopathology from the study of feeblemindedness to drug addiction. She deals historically with the various theories of neurosis, and such neglected writers as Janet, Babinski, Hurst, Rosanoff, and Rivers are given due attention in addition to the more familiar Freud, Adler, and Jung. The volume is comprehensive and there are very few conditions and psychological theories which are not described and criticised. The most critical pages of all are devoted to the Freudian psychology; the fact that references to this school are directed against the "psycho-analogical viewpoint" will irritate many readers. It is obvious that the investigation of psycho-analysis which underlies the criticisms has been extremely superficial, with the result that Freud's concepts of unconscious symbolism and the use of dream analysis are regarded as mysticism and demonology. The very fact, as Prof. Hollingworth states, that psychoneurotic disorders have been cured by all forms of charlatanry and suggestion may invalidate every theory of explanation, but she appears to forget that psycho-analysis itself has not failed to give a reasonabl explanation of the mechanism of suggestion and th charlatan. The simple theories which she prefer to psycho-analysis are simple largely because she ha made them so, and has not subjected individua cases to prolonged investigation. The findings o psycho-analysis satisfy not only the problems o psychopathology to a high degree, but shed a ligh upon many human institutions. On this latte support of psycho-analysis she makes little commen No theory has finality, but up to date the Freudia hypotheses are based upon as prolonged and scientific an investigation of the facts as any oth theory, and seem to explain more of the facts.

Emigration, Migration, and Nomadism.

By the late WALTER HEAPE. Edited with preface by F. H. A. MARSHALL. Cambridg W. Heffer and Sons. 1931. Pp. 369. 12s. 6d.

A PLEASANT portrait of Heape forms the front piece of this characteristic book. He was origina an embryologist; students of Quain's Anatomy w remember his pictures of the early development the mole. But before he was 35 he had brok away from the conventional methods and became pioneer in the study of the physiology of generatio activating en route Dr. F. H. A. Marshall, who ed this book, which Heape left a little short of completi when he died in 1929. He deals with the journe of animals from which a return may be anticipat (migrations), their movements by which they p manently evacuate a territory (emigration) and th wanderings at random, and incidentally an ext ordinary range of germane and allied topics in whi any naturalist or student of human behaviour w be much interested; man himself is excluded fr the scheme. The background on which all t wealth of detail is arranged is sexual physiology a Heape's inductive belief in some kind of generati ferment which animals could apparently abso from their surroundings; we can imagine the delig with which he must have welcomed Evans and Bur discovery of vitamin E in 1925. We call the bo characteristic of Heape because it is gentle, huma and scholarly. It is also exceptionally interestin whether it deals with the bear's conception of ter tory, or with the migrations of Painted Ladies, tells how Stefansson sat over his seal hole in perf confidence that his daily bread must sooner or lat come up to take a breath of air.

THE LANCET.

LONDON: SATURDAY, MARCH 5, 1932.

YOUNG OFFENDERS.

In 1927 the Government of the time appointed Departmental Committee on the Treatment of oung Offenders. It was then recognised that ie reformation of the offender had become the ;ynote of the administration of justice, and that :oportionately greater stress should be placed pon the need for reformation of the young offender uring the years of mental plasticity. As the sult of their careful deliberations, the Committee me to certain definite conclusions of which ie following were some of the most important. rst, that the magistrates sitting in the juvenile urts should be specially qualified for the work, at there should be a pooling of their experiences, id that they should make themselves fully quainted with the institutions to which children e sent. Secondly, that the whole procedure of ch courts should be remodelled in the direction simplicity; that the court should be in possession full medical and scholastic reports, should work close coöperation with educational authorities, id should not be situated in premises used for her courts, and that these latter should be able refer a person under 17 to a juvenile court. hirdly, that much better facilities should obtain r the examination of young offenders, and that least three central remand homes should be tablished for this purpose, but wherever possible e fullest use should be made of bail. The ommittee also stressed the importance of probation the open rather than in institutions; the wider e of hostels was urged. No sentimental ideas wever were encouraged with regard to proation; supervision by women for girls, and men r boys was recommended. The Borstal system as praised, but it was urged that children should sent there for *training* and not "*sentenced to tention under penal discipline, &c.*" The age r capital punishment was recommended to be ised to 18. As regards mental defectives, the ave lack of accommodation was emphasised, nd the pathetic case of the post-encephalitic ffender was mentioned as calling for special eatment on purely medical lines. While these oints do not exhaust all the excellent recomendations made by the Departmental Committee ey do include all the points of interest to medical en who are or may be directly concerned with uch children as come before juvenile courts.

The Children and Young Persons Bill now efore the House of Commons is substantially ased upon the recommendations of the Committee f 1927.

In future the court shall not be associated with the remises of a police station or adult court, and the magistrates are to be chosen from a panel of those specially qualified to deal with juvenile cases.

The age of young offenders or those needing specially guardianship who appear before a juvenile court will be raised to 17.

In the place of the two categories of schools (industrial and reformatory) there shall in future be one class (approved schools), to which children are to be sent for a period of three years, but if under 11 years of age they may be detained until the school-leaving years.

The age of capital punishment is to be raised to 18, and the adult courts are to have the power to remit juvenile offenders to the juvenile court.

But while the Bill illustrates the fact that time has worked a change towards the appreciation of the special needs of young offenders, it has singularly failed to take into account the medical, psychological, and sociological advances that have been made in the field of juvenile delinquency. Pædiatricians, psychiatrists, and social workers who are in daily contact with the neurotic and behaviour disorders of children and of young adolescents, are witness to the multiple factors that go to make up the mentality of the so-called difficult child. They are aware that while society must expect of its members a reasonably high degree of conformity to social usages, it is impossible to apply to young people the same legal categories as are applied to adults. Moreover, during the years of mental plasticity, before social sentiments are established, the child as a labile organism is only too easily influenced by medical conditions, sometimes gross, sometimes subtle, and by environmental factors. Above all, there are individual reactions to family stresses born of temperamental peculiarities which have to be carefully assessed before remedial measures can be applied. Delinquency as much as neurosis is a function of the personality in its interplay with environmental forces. Only expert study of this interplay can reach an understanding of the forces at work and apply a suitable remedy. In Belgium, the Government has established at Moll an institution which is nothing less than a research station; to this young offenders are sent and here their problems are studied by an expert staff before they are sent to places of detention according to the character of the disorder from which the child and adolescent is presumed to be suffering. There is unhappily no indication in the present Bill that any consideration has been given to the all-important subject of diagnosis upon which adequate treatment shall be based. In some of our juvenile courts, the presiding magistrates have invited the coöperation of psychiatrists who have experience in child psychology from their practice in the child guidance clinics and analogous treatment centres. Their value has been proved in many cases. They have sometimes in a side room of the court—or more often in their clinics when cases have been put on bail or probation—disclosed medical and psychological factors which explain the offence. They have discovered family conflicts and environmental stresses from which the child in his dilemma has escaped along the path of delinquency. In addition they have been able to give valuable guidance to probation officers

SONERYL

TRADE MARK

Powerful Hypnotic and Analgesic

An agent which has the double advantage of relieving pain and inducing sleep is invaluable in everyday practice.

"Soneryl" adequately meets this need and is widely employed for insomnia, whether arising from painful affections or febrile or nervous states.

"Soneryl" produces no after-effects nor does it lead to habit formation.

Supplied in tablets for oral use and ampoules for intravenous or subcutaneous injection.

ears and their scale might easily become larger. he cost in death and disability has not yet been ery great, but it should be generally realised at a high proportion of our endemic cases are f the epidemic (acute febrile) character, and thereore susceptible of preparalytic diagnosis and eatment. The means should be ready to hand

USE OF TUBERCULIN IN DIAGNOSIS.

Nearly forty-two years have passed since och introduced the substance now universally nown as "old tuberculin." It failed to live up expectations as a specific cure for tuberculosis, nd seven years later Koch himself abandoned it n favour of "new tuberculin." From that time nwards the ingenuity of the immunologist has eadily added to the number of tuberculins ntil confusion has become worse confounded. ut whatever may be the verdict of posterity n their value as remedies, it seems pretty clear at Koch's old tuberculin is useful in diagnosis. f the tuberculin tests used in clinical practice the ne introduced by Pirquet in 1907 was *facile rinceps* until after the war. It has passed through any vicissitudes of obloquy and praise and, lthough leading exponents of tuberculin diagnosis, ch as Hamburger, have demonstrated its llacies, it is still extensively used in many lands, ough not very largely in this country. In 908, Mendel and Mantoux independently introuced the intradermal test, which, though dmittedly more precise, failed to attract much ttention until after the war. Since then it as come to its own as the most reliable and ccurate of the tuberculin tests, largely as a result f extensive records compiled in America. In valuable report issued last week, Dr. P. D'Arcy art[1] has explored much of the new work and ondensed it—a very considerable achievement—nd also records a tuberculin survey of London hildren which may be compared with those recently ublished by W. F. Gaisford from the East ondon Hospital for Children and by D. J. Dow and E. Lloyd from the Brompton Chest Hospital. glance even at Dr. Hart's bibliography leaves feeling almost of dismay in the minds of those amiliar with the solid, red-paper-covered volume f Bandelier and Roepke which was the great tand-by of the early days.

With some of the issues raised by these modern evelopments we have already dealt.[2] Three t least may be underlined as important: 1) the relative value of the various fractions of rude tuberculin which have been isolated during he last few years; (2) the records of the tuberulin surveys as evidence of the prevalence of uberculosis in both large crowded communities nd in small isolated units; and (3) the sociological significance, from the standpoint of the mmunised community, of the negative reaction, specially as regards the "contacts." To these, Dr. Hart would presumably add a fourth, for he asks the reader to reconsider the tuberculin skin reaction as a means of clinical diagnosis in relation to the new Mantoux test. The first question is of a highly technical character, and must be left to the immunologists and biochemists to work out, but light is thrown upon it by Dr. Hart's observations[3] on the incidence of skin sensitiveness to glycerinated veal peptone broth (the medium used in preparing old tuberculin) and its relation to tuberculin sensitiveness. Of the second question more needs to be said. In surveys of whole communities, especially of school-children, the intradermal test has been used to amass vast columns of statistics. It was necessary that it should be done for each country, but we confess to the hope that the spate of uninspired arithmetic will soon diminish, for we doubt if a few odd thousand more children added to the tally will help matters much. Probably most clinicians of experience will agree with the view that a positive tuberculin reaction means that the person has at some time been affected with the tubercle bacillus, but, as Dr. Hart admits, no more stringent conclusions can be drawn than this. Comparing some of the earliest tuberculin surveys with the more recent he says that in the former surveys there seemed to be an assumption that among the poorer classes of some European and American cities there was a very high proportion of tuberculin positives in late childhood, whereas recent figures with the intradermal test show considerably lower percentages. Is this due to differences in technique, or is it due to an actual reduction in incidence of tuberculous infection in childhood? He also suggests that these systematic tuberculin tests on children may throw light on a new clinical entity—transient and benign illness accompanying tuberculous first infection.

As a means of investigating contacts the test has been abundantly justified by the data produced. Some of the figures are astonishing. In Oslo, for instance, J. Heimbeck[4] tested with the Pirquet reaction probationer nurses of the ages 20 to 25 entering the Ullevaal Hospital, part of which consists of beds for tuberculous patients. Of 282 nurses who began with a positive Pirquet reaction four developed tuberculosis, whilst of 299 who began their training with a negative reaction 67 became tuberculous. Some confirmation of these figures is given by E. K. Geer[5] from hospitals in the State of Minnesota where the incidence of tuberculous infection in young adults seems to be low. Since September, 1928, he has tested all incoming probationers at the Ancker Hospital in the city of St. Paul, Minnesota, 215 out of the 975 beds in the hospital being allotted to tuberculous patients. Thirty per cent. of these nurses showed positive reactions to the intradermal test on entering the training school, and practically all gave a positive before they had completed their three-year training period. The records of these nurses indicate that the negative in charge of cases, and have saved curable cases from years of confinement in reformatories and industrial schools where no classification can be made, or rarely is made, and where the treatment must be more or less standardised.

---

The outstanding omissions from the Bill are therefore, first, the need for observation centres in the place of the present remand homes, at which centres diagnosis of the condition can be made after expert social and psychological data have been collected. Secondly, the need of the presence in an official capacity in juvenile courts of trained psychiatrists to aid the magistrate in disposing of cases after the charge has been substantiated. Lastly, no provision is made in the Bill for the establishment of an adequate service of probation officers trained in the ground-work of family psychology and social conditions and possessing the type of personality which is only too rare in this type of work. Many who do this work in connexion with various voluntary bodies are poorly paid and succeed largely because of their enthusiasm for work of deep social importance. Those in authority must surely recognise that the progress of modern pædiatrics and psychology is not the work of yesterday, but is the result of the accumulated knowledge of the last 50 years. The philanthropic zeal of the prison reformers has been richly supplemented by a growing body of knowledge with regard to the motives of disorders of conduct. The foundations of personality are laid in childhood, and to correct the disorders of personality in the early years of childhood or at least in adolescence is to lay the foundations of good citizenship and so to relieve the courts of adult cases who return again and again because early measures have not been adopted to deal with social evils at the root.

THE DIAGNOSIS AND TREATMENT OF POLIOMYELITIS.

Poliomyelitis does not present quite the same problem in England as it does in Australia, but no one can afford to ignore the lessons of the Melbourne epidemic. Dr. Jean Macnamara and Dr. F. G. Morgan conclude their account of it in our present issue, and their paper defines very clearly our responsibilities towards victims of this disease. The story is highly encouraging, but Melbourne has evidently set a standard to which we cannot attain without a definite effort. In Australia the reward of such effort has been very great.

The practitioner will find the report interesting, first because it brings out clearly the possibility of diagnosis before the stage of paralysis and describes in detail the means by which this early diagnosis can be made. Attention is directed towards the signs and symptoms of the prodromal feverish attack and especially to the "spine sign" which signifies impending paralysis. Lumbar puncture, it is emphasised, must be undertaken only if the warning indications of cerebro-spinal involvement are present. Premature disturbance of a sick and feverish child is well avoided. but it is not discomfort only that is to be feared. For lumbar puncture, done in a genuine case of poliomyelitis before the meningeal irritation has provoked the characteristic reaction, will be misleading and may also upset the delicate relations between the cerebro-spinal fluid and the pia-arachnoid and thus favour spinal infection. That lumbar puncture tends to increase the permeability of this last line of defence is insufficiently appreciated; *indeed, early puncture is often ardently* advised. Evidently this is to be deprecated; on the other hand it cannot be too strongly emphasised *that lumbar puncture in a suspected* case of poliomyelitis is urgently required as soon as there are signs of the central nervous system being involved. Dr. Macnamara is also emphatic that the examination of the fluid should be done there and then, at the bedside, and that immune convalescent serum should be injected without removal of the needle if the diagnosis is positive. Delay in giving serum may be very serious or disastrous. But if the supply of serum is unavoidably delayed it seems to be better to await its arrival, and then do the lumbar puncture, rather than prove the diagnosis by lumbar puncture and *then* wait for the serum. The serum itself must be free from any toxic or irritating substance, so that neither a general febrile reaction, nor a local spinal or meningeal irritation, may disturb the clinical picture. The result of an adequate dose should be a prompt and progressive fall of temperature and clinical improvement; unless this takes place a further dose must be given promptly, and the decision is not at all easy to make if the serum has properties beyond its immunising effect. Macnamara and Morgan therefore prefer human to horse serum, and they use serum prepared and preserved with the utmost precaution but without antiseptics. Obtained from old cases, it is pooled and tested from time to time against virus. Its therapeutic powers are almost magical. On the system which Dr. Macnamara adopts, the aggregate paralysis of each case can be expressed in figures and the contrast between treated and untreated cases is astonishing. The records are all the more convincing in that the majority of serum cases show a paralysis aggregate numeral, though a very small one, indicating that the virus succeeded in reaching the anterior horn cells and that they were true, not abortive, cases of poliomyelitis.

England seems to have been the first European country to harbour the disease (1784, Underwood) which was said to be of Asiatic origin. It was not recognised until 1840 on the continent (Heine) and until 1841 in America (Medin). We had indeed a start, but probably a short one, and this is of interest because some hold that we have become relatively immune as a race and therefore need not fear the serious epidemics from which other countries suffer. Whether the prolonged endemic persistence of poliomyelitis *has given some* degree of immunity, or the cool climate is in our favour, we do not know, but it would be easy to have an undue sense of security. There have been various small epidemics in this country in the last five ncome of all hospitals. With the increase of contributory schemes and paying wards these contributions may tend to disappear. The crux of the whole position is found in the disposal of funds made available to hospitals through contributory schemes, the term being used in its widest sense, and the committee asks two pertinent questions:

> (a) Are members of existing contributory schemes paying at this time enough to meet the cost of their maintenance while in hospital and to provide a contribution towards the remuneration of the visiting medical staff?
>
> (b) Is it practicable at this moment of unexampled financial stringency and unemployment to suggest a higher rate of contribution?

Conditions are not uniform throughout the country, experiments are still being made by individual hospitals, and a natural process of growth and adjustment is in evidence. The committee thinks it would be an error to attempt to drive the more backward regions to seek to hold back the more progressive, or to insist upon absolute uniformity between hospital and hospital. Apart from this there is general agreement on the payment to the visiting medical staff of a part of funds paid on account of in-patients and out-patients by the State, county or municipal or other public authorities, or by accident insurance companies.

The joint committee registers its conclusions: (1) that the time has come to recognise the claim of the visiting medical staffs to some share in the moneys raised for the treatment of patients in hospital, other than those provided by voluntary subscription or donation for the treatment of free patients; (2) that the ideal contributory scheme is one in which the individual shall contribute upon a basis designed to provide (a) cost of maintenance, (b) something towards the remuneration of the visiting medical staff; (3) the provision in all suitable hospitals of a sufficient number of rooms or wards for paying patients, coupled with the strict application of a maximum means test for entry into general wards.

THE GERMICIDAL POWER OF THE SKIN.

Two years ago L. Arnold and co-workers[1] came to the conclusion that the skin has some power to destroy bacteria. In further experiments on the same subject J. F. Norton and M. N. Novy[2] have closely followed the technique they described. The hands were immersed in a dilute suspension of *Bacillus prodigiosus*, and from the surface thus infected agar plates and broth tubes were inoculated after various periods. The colonies which grew were counted, and the results were carefully recorded. As might have been expected, the factors of moisture or dryness had a big influence. During the experiments it was found that the skin usually became dry in ten minutes, and whereas, in a series of 12 experiments on the dorsal surface of the hand, there were apparently no organisms left after half an hour, as many as 150 to 1000 colonies could be counted when the skin was kept moist by water vapour. Other materials, such as glass, filter-paper, and tanned hide were tested in the same way and found to give closely similar results, from which it is concluded "that these experiments fail to indicate any inherent germicidal power of living skin." Apart from their surgical and hygienic bearings these results are of dermatological interest. If moisture favours the growth of bacteria—and of this there is, of course, no doubt—it is easy to understand the part it plays in producing such conditions as washerwoman's dermatitis, tinea cruris and pedis, and the various forms of intertrigo, whether due to bacteria or fungi. This knowledge supports experimentally the value of desiccating or exsiccating remedies like spirit, powder-containing lotions, and absorbent powders. Equally significant are the evil results of too much moisture, and the occlusory effects of grease and ointments in the intertriginous type of case.

EUTHANASIA.

LAST October we reported[1] Dr. C. Killick Millard's presidential address to the Society of Medical Officers of Health, in which he pleaded for the legalisation of euthanasia. He has now reprinted his paper in pamphlet form,[2] together with the text of his proposed Bill and an appendix containing expressions of opinion by doctors, clergymen, and others. Sir W. Arbuthnot Lane, in a foreword, strongly supports Dr. Millard's views, and says he has met with widespread approval of them in the audiences, chiefly composed of working people, whom he has addressed. He points out, however, that it will probably be difficult to pass the Bill rapidly through the House of Commons, and the *Spectator* in an editorial article last autumn probably came even nearer the truth when it said that the Bill stood not the smallest chance of passage into law at present. Nevertheless, the drafting of a serious Bill is a good method of stimulating public discussion in a subject as important as this. Dr. Millard produces a considerable number of thoughtful opinions in favour of the legalisation of euthanasia subject to adequate safeguard, but only gives, as an example of adverse criticism, four extracts which on the face of them would not be likely to command much respect from reasonable minds. Surely a movement as novel and daring as this has evoked as weighty criticism as it has approbation? If Dr. Millard has received any expressions of adverse opinion at all comparable with the favourable ones he quotes, it would probably help his cause if he were to publish them.

THE TOURNIQUET.

IN the last issue of the *British Red Cross Quarterly Review* there is a tale with a moral to it. A woman had been knocked down by a bicycle in the street, and had a nasty cut a little above the left eye. An errand boy, who had secured a front-row position, asked anxiously: "Aren't you going to stop it with a tourniquet?" Most first-aid manuals take the tourniquet for granted, and give first-aid workers a vague and diplomatic warning about the dangers of too prolonged pressure without, as a rule, mentioning any time limit. Few, if any, authors of such manuals ignore the tourniquet altogether or to refer to it as a disreputable relic of the past, whose only habitat should be the museum. This is, however, the gist of the opinion expressed by Dr. M. Stassen in *Bruxelles-Médical* for Dec. 13th, 1931. During the past seven years he has dispensed with the tourniquet in the first-aid equipments for which he has been responsible, and among the several hundred cases of compound fractures of the limbs brought to his hospital from points up to 60 kilometres distant, he has not once had a death from hæmorrhage during transport. Belgian army surgeons formed a very bad opinion of the tourniquet during the Great War, and Dr. Stassen regards this instrument as a frequent reactors at the end of the childhood period are virgin soil for adolescent infection. The investigation of R. J. Matthews in Wales points in the same direction, though unfortunately, like Heimbeck's figures quoted above, his records were obtained with the old Pirquet test and are therefore not strictly comparable with Geer's. Following up a number of child contacts over a period of years Matthews found that in a group of 120 cases there was no tuberculosis in the tuberculin positive group, whereas in the negative group there were seven cases which subsequently developed tuberculosis, six of them on reaching adolescence. There is good evidence therefore that non-reactors cannot merely be dismissed with the verdict "all is well." Their chance of subsequently developing clinical tuberculosis is greater than that of the reactors. With regard to tuberculin as an aid to clinical diagnosis Dr. Hart states that a positive response in infancy more than at any other age suggests a tuberculous infection which is likely to be progressive, and that clinical tuberculosis is, or soon will be, present, and moreover that the outlook is unfavourable. A positive reaction in children aged 2 to 5 *with symptoms* is also of significance, but, in Dr. Hart's opinion, the interpretation of the positive reaction in those over five years of age requires considerable experience and at the present stage defies dogmatism. We are not sure, however, that we should like to go all the way with him in saying that the diagnosis of *tuberculosis in childhood* should never be made without performing a tuberculin test unless there is clear bacteriological or pathological evidence of disease. These positive reactions, too, like the positive Wassermann, may prove actually a red herring. Dr. Hart makes a valuable point when he states that in certain cutaneous conditions, such as lupus pernio and the sarcoids, a loss of tuberculin reactivity may be found, so that a positive response is evidence against the diagnosis, whilst a negative response, demonstrated by the intradermal test in maximal doses, strongly supports the diagnosis.

[2] Euthanasia: a Plea for the Legalisation of Voluntary Euthanasia under Certain Conditions. By C. Killick Millard, M.D., D.Sc. London: C. W. Daniel Company. Pp. 44. 2s.

Although Dr. Hart is both wisely conservative and scrupulously careful to avoid extravagant claims he has shown that much remains to b done. Tuberculin diagnosis is not the close chapter it was thought to be even a decade ago The next advance seems likely to be along laborator lines. During the last few years important step have been taken in standardisation, and quit recently a team investigation has been starte in America which has already made importan contributions in the fractional investigation tuberculin products.

ANNOTATIONS

HOSPITAL STAFF PAYMENT.

The question of paying the visiting medical staffs of voluntary hospitals has been advanced a stage by the issue of a report[1] by a joint committee of the British Hospitals Association and the British Medical Association. Institutional treatment, it is remarked, has largely displaced treatment in the home, and is tending to do so more completely. At the same time social status and private means are counting less as reasons why any patient should or should not go to hospital. This substitution of institutional for home treatment has restricted the private practice of consultants and specialists, who find it increasingly difficult to earn a living without raising their private fees. The narrowing of this field of private practice shows signs of bringing about a reduction in the numbers of consultants and specialists who are in a position to give gratuitous service to the voluntary hospitals—a tendency regarded as likely to increase. The effect of competition with the municipal hospitals is then considered.

Under the Local Government Act, 1929, local authorities may finance hospitals not only for patients of the poor-law category, but for the whole community. Such council hospitals might be staffed by part-time consultants as well as whole-time medical officers, both on a salaried basis. Their management might be in the hands of representative committees, and they might be associated with teaching schools. They might thus closely approximate to the voluntary hospitals while enjoying the powerful advantage of drawing their financial support from public funds. Again, such council hospitals may, in accordance with the terms of the Act of 1929, receive subventions from contributory schemes on account of treatment given to contributors. In the case of patients able but unwilling to pay for their treatment, council hospitals may recover payme by legal process. The constantly extending demand f institutional treatment, coupled with the shortage (in mo areas) of hospital accommodation, makes it, in our opinio very probable that local authorities will in the course time contemplate ambitious schemes for the provision beds for other than p [illegible] But whether not this proves to be t [illegible] to believe th the existence of public [illegible] ith paid who and part-time visiting medical staffs will not have a power influence in the direction of strengthening the demand f payment by the visiting medical staffs of volunta hospitals.

The problem accordingly resolves itself into t devising of means whereby all voluntary hospit patients who can afford to do so may make a reaso able contribution towards the fees of the docto who treat them as well as towards their maintenan while in hospital. The case of paying patien presents little difficulty, for it is self-evident that patient whose means enable him to pay for treatme as a private person should be allowed to enter t general wards of a hospital. The provision in suitable hospitals of a sufficient number of rooms wards for paying patients, coupled with the stri application of a maximum means test for entry in general wards would, it is felt, have an importa bearing upon the position and attitude of the visiti medical staffs. To what extent *such provision* already available in the London area may be se from a list of pay beds, revised up to the end 1931, and just issued[2] by King Edward's Fund. T joint committee commends the *matter* to the attenti of hospitals in which such accommodation is capab of extension or has not yet been introduced. Co tributions obtained directly from patients throu the efforts of almoners during or after treatment a said to constitute about 10 per cent. of the aggrega an experiment in the prevention of the common ld by means of a vaccine. In the experimental oup were 80 medical students, and in the control oup were 82. He concludes that the statistical sults of the experiment show little, if any, advantage to the experimental group. The mean number f colds suffered by the experimental group (over ven months) was 1·85, with a mean duration of ·4 days, while the corresponding figures for the ontrol group were 2·17 and 7·6. These figures do ot differ significantly, but on the other hand the stimated average duration of colds during the preious years amongst the experimental group was 0·5 days, while the same average for the control roup was 7·6 days. This suggests that some improvenent may have taken place amongst the experinental group, but it also points to the weakness of he investigation. Any method of investigation that llows the experimental group to be unduly weighted vith "susceptibles," as is here apparent, must be nsatisfactory. To prove that the groups are comparable with regard to such factors as the amount f water (and/or alcohol), tobacco, chewing-gum, and ice-cream they consume, the time when they go to bed, and the number of baths they take weekly (to mention but a few for which this paper provides statistics), seems an idle refinement in the face of such a fundamental difference with regard to susceptibility as is suggested by the previous histories of colds.

ACCIDENTS AND HOSPITAL CONTRIBUTORY SCHEMES.

MOST of the annual reports and meetings of the provincial hospitals which come thick and fast at this season are concerned with the burden placed upon them by road accidents. In a recent broadcast speech Lord Moynihan stated that Leeds Infirmary is losing £2000 a year in this way; Bradford Infirmary last year spent £600 more than it recovered upon such cases; Southport Infirmary lost £373; the Devon and Exeter Hospital complains that the suggested uniform charge of seven and sixpence a day for the treatment of victims of road accidents is "totally insufficient." In every part of the country the story is similar, and in some places contributory schemes are becoming inadequate to meet the swollen expenses, in which motor accidents are one of the items. Birmingham has already raised its contribution; Sheffield is thinking of doing likewise; and the Merseyside Hospitals Council is seeking to widen its scheme by, among other means, appealing for those annual subscribers who in most places show a tendency to fall away. Just now Liverpool is having a rather unhappy experience. Last year its port sanitary and hospitals committee spent nearly £37,000 in excess of the estimates, almost the whole of which was attributable to capital expenditure upon transferred institutions to bring them into line with the modern type of hospital. Meanwhile Liverpool, undaunted, is hastening the completion of its new Samaritan Hospital for Women which is to cost about £150,000.

Contributory schemes, under various names, are becoming increasingly important to every hospital fed by them, and several new ones are being launched. An outstanding example of success is the Leeds Hospital Fund which last year increased its income by £10,500; it now exceeds £56,000. In ten years the workpeople's hospital committee of Gloucestershire Royal Infirmary has raised just under £100,000; last year the Torbay Hospital contributory scheme collected over £7000; in 1931 the Exmouth and District Hospital League increased its membership by 1537; the Newton Abbot contributory scheme, with over 5000 members, brought in £1500. In view of these and similar figures there is small wonder that other hospitals of varying degrees of importance have decided to establish contributory schemes. Thus Walsall General Hospital, the scene in its early cottage hospital days of the devoted labours of "Sister Dora," sees no other way of making necessary enlargements, and it is proposed to make a reciprocal arrangement for treatment of its members with the neighbouring Wolverhampton Royal Hospital which has recently established a highly successful scheme with a large basis of miners. Simultaneously Goole is considering a scheme that would enable its Bartholomew Hospital, in return for a contribution of twopence a week, to give free treatment to persons whose weekly income is under £5, with special arrangements for the neighbouring villages. Since Wolverhampton has 210 beds, Walsall 100, and Goole 24, the advantages of a contributory scheme are seen to appeal to hospitals of very varying dimensions.

DISTRICT NURSING IN LONDON.

IN her survey of district nursing in London, published by the London County Council last year, Dr. Margaret Hogarth paid a remarkable tribute to the thoroughness with which care of the sick poor in their homes is organised. "I was impressed," she wrote, "with the tremendous amount of individual and collective voluntary effort expended in securing for the poorer classes a free nursing service of the highest quality obtainable. This service is never denied to anyone who cannot pay for the services of a private nurse. . . . The qualifications of the nurses employed are the best obtainable in the nursing profession." Much of the responsibility for coördinating the work of the different bodies engaged in domiciliary nursing falls upon the Central Council for District Nursing, a voluntary organisation founded for this purpose in 1914. Nursing care for the sick poor of London in their homes is provided in three ways: by district nursing associations, either independent or affiliated to the Queen's Institute; by nurses attached to the nursing branch of the Ranyard Mission; and by a few parish nurses. It speaks highly for the work of the Central Council that Dr. Hogarth found only one part of London—the new Grove Park Estate—uncovered by the organisations now at work; and even there steps were being taken to provide a nurse. The changes in administration following the enforcement of the Local Government Act of 1929 could not fail to affect the position of the Central Council to some extent, and at the end of 1929 a deputation was sent before the London County Council to explain the Central Council's work and to offer their experience and machinery for the distribution of any future subsidy which might be made to district nursing in place of the inadequate and unequal grants previously given by the boards of guardians. The annual report of the Central Council for the year 1931 tells us that a committee was formed by the London County Council to consider the question of grants, but that no definite conclusion has so far been reached. The decision can hardly fail to be one of grave importance to district nursing organisations, since the economic crisis makes it increasingly difficult for them to obtain financial assistance. It is significant of their position that the City Parochial Foundation in making cause of traumatic shock and gas gangrene. By completely arresting the circulation in the injured limb, the tourniquet promotes infection in the crushed and torn tissues, and its removal is followed by absorption of toxic products capable of killing a patient already weakened by cold, shock, and loss of blood. At The Hague in 1931, during the sixth International Congress of Military Medicine and Pharmacy, various speakers condemned the tourniquet in unequivocal terms. Colonel Praag on this occasion declared that the medical personnel cannot be taught too much about the dangers of the application of the tourniquet which should not be permitted in any but cases of extreme urgency. In his report on the "Action du garrot sur le choc traumatique" Colonel Dante Casella was not less emphatic on the same occasion. The errand boy, it would seem, is now the staunchest friend of the tourniquet.

NEW NAMES FOR HOSPITALS.

ASCENDING for once from the practical to the romantic, the London County Council decided to improve the names of some of its hospitals by abandoning the territorial and utilitarian in favour of something more aspiring. It has, however, chosen the new designations with a nice regard for local susceptibilities which, even in London, are properly tender. Resisting the temptation to call its hospitals after their chairman or vice-chairman, it has entered the safer field of hagiology. St. Leonard of Shoreditch, St. Alphege of Greenwich, and St. Olave of Bermondsey are names which belong to local history. The comparatively unfamiliar St. Benedict will illuminate the hospital at Tooting which will thus be able to realise a spiritual relationship with the St. Benet to whom the City of London dedicated four of its ancient churches. The Hospital of St. Nicholas, beloved of fishermen, carries on the traditions of Plumstead: but St. Charles of Marylebone seems to be more picturesque than locally appropriate. Only two saints of that name appear to be known to the Churches—the Roman St. Charles Borromeo and the "Charles, King and Martyr" of the old Anglican calendar, to whom some five or six churches have been dedicated. That houses of healing should be given distinctive names suggestive of the spiritual basis of hospital work is all to the good. But it rests with the staff of these institutions to make the new designations so familiar that we shall speak, for instance, of St. Olave's without the need to mention Bermondsey.

RELIEF OF VESICAL IRRITATION.

As a remedy for painful conditions of the bladder, B. E. Greenberg and M. L. Brodny[1] have been using mineral oil sterilised in the autoclave, cooled and then heated to body temperature. Some 4 oz. of the oil are injected slowly into the bladder, and despite the fact that patients with cystitis suffer from increased frequency—partly because of their condition and partly because they are on "forced fluids"—some of it may remain there as long as a week. After its instillation the vesical irritation, tenesmus, and frequency are reduced; as the burning decreases the patient loses his fear of micturition and consents to drink the large amount of liquid required for adequate therapy. Greenberg and Brodny have used this method not only for ordinary cystitis, but also for tuberculosis of the bladder. They have, moreover, found it useful in alkaline cystitis where the bladder wall is encrusted with phosphates; the oil loosens the encrustations and cleans up the bladder. In a previous paper[2] Greenberg has advocated the use of sterile mineral oil as a medium for cystoscopy, finding that with irritated bladders far better distension could be obtained with oil than with boric lotion. Furthermore, the intense discomfort which often follows cystoscopy in such cases was prevented. Finally, the oil was found to encourage hæmostasis so that cystoscopy could be undertaken in the presence of bleeding that would otherwise have obscured the view. The method is a simple one, and these claims are so striking that it certainly deserves a trial.

PROBLEMS OF RESPIRATORY DISEASE.

RECENTLY we quoted observations on draughts and colds published by Winslow and Greenburg in the January number of the *American Journal of Hygiene*. The same issue contains several other papers on various aspects of respiratory disease. Janet M. Bourn reports a further study of the occurrence of *Hæmophilus influenzæ* (Pfeiffer's bacillus) in Baltimore, based upon 2600 nasopharyngeal cultures. The bacillus was isolated with no greater frequency from cases of respiratory disease than from healthy persons. In addition, during 1928–1929 a widespread epidemic of influenza took place. The incidence of *H. influenzæ* was no higher in these epidemic months than in the following non-epidemic year, a result in agreement with the conclusions of the report published by the Ministry of Health in 1930 on the nasopharyngeal flora of a group of the Manchester population.[3] On the other hand, in the English study there was no evidence that the onset of a cold was associated with any characteristic change in the nasopharyngeal flora. In Bourn's investigation a more detailed study of cases of upper respiratory disease (which included influenza and other symptoms besides the common cold) showed a higher frequency of the bacillus amongst those with more extensive local symptoms. For example, the bacillus was found in 28 per cent. of cases with cough and in only 16 per cent. of cases without cough, a difference which is unlikely to have arisen by chance. This difference and a tendency to a greater frequency late in the attack in all cases support the general belief that this particular bacillus is of importance as a secondary invader. Frequent examinations showed that practically all persons of the classes studied harboured *H. influenzæ* at some time during the two years.

With regard to the pneumococcus, Selma M. Shultz found the duration of the carrier state amongst 35 children convalescent from pneumonia to vary between 2 and 152 days. She considers that the convalescing child, possibly carrying the pathogen in its throat for such long periods, may well be considered a potential source of respiratory diseases in others. For 21 children with pneumococcal pneumonia she endeavoured to measure the incidence of pneumococcus carriers amongst contacts. Naturally the search had to be limited to the most intimate contacts, and amongst these (86 in number) 13 per cent. produced the same type of pneumococcus as that isolated from the pneumonia patient. No significant variation was apparent in the virulence of the bacillus isolated from the cases and the corresponding carriers.

In a third paper W. E. Brown gives the results

SPECIAL ARTICLES

POLIOMYELO-ENCEPHALITIS
IN VICTORIA (1925–1931).
TREATMENT BY HUMAN IMMUNE SERUM.

By Jean Macnamara, M.D. Melb.,

HON. MEDICAL OFFICER TO THE PHYSIOTHERAPY DEPARTMENT, CHILDREN'S HOSPITAL, MELBOURNE; CONSULTANT TO THE VICTORIAN COMMITTEE FOR POLIOMYELITIS, APRIL, 1925, TO AUGUST, 1931;

AND

F. G. Morgan, M.B. Melb.,

DIRECTOR, LABORATORIES DIVISION, COMMONWEALTH DEPARTMENT OF HEALTH, AUSTRALIA.

(Concluded from p. 472.)

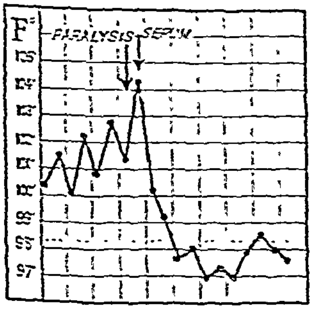
Results of Serum Therapy.

During the period under review serum has been administered to 260 patients. When a patient has sought treatment within 24 hours of the advent of paralysis, if *fever persisted an intravenous injection* of 40–60 c.cm. of serum has been given. The usual but not invariable sequence has been an immediate fall of temperature and arrest of paralysis at the stage existing when the injection was made (Fig 4).

During the months November, 1930, to July, 1931, an epidemic of 270 cases occurred. This excited great public interest. In Melbourne, where most of the cases were, families are not large: children are valuable. The press, authorities of schools, kindergartens, infant welfare centres and similar organisations, united in impressing upon parents the necessity for early diagnosis. Hundreds of children, on the slightest evidence of malaise, were taken to their doctors or to the out-patient departments of public hospitals because the parents feared paralysis. The general practitioners, many of whom had seen cases in previous years, had special lectures and demonstrations, and watched every patient suffering from indefinite illness very closely for the development of a spine sign or other warning symptoms. While it is possible that a few cases were missed, the widespread interest of public and profession makes one confident that the number of sick children not attended by a member of the profession during that period was negligible.

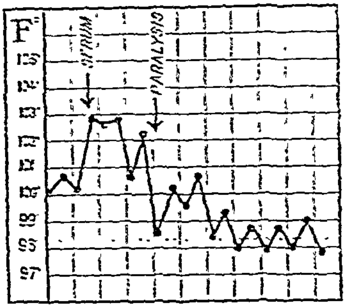
It is admitted that the only accurate method to assess the results of any therapy in preparalytic poliomyelitis would be the treatment of alternate cases, leaving the remainder as controls. In Australia this could not be done. Of the 270 cases of the epidemic, 254 were seen by one of us (J. M.), who was responsible for the after-treatment of the majority of paralysed cases by means of splinting and muscle re-education. It appeared, therefore, that an opportunity was presented to compare the cases treated with serum in the preparalytic stage with the remainder of the cases of the same epidemic.

FIG. 4.



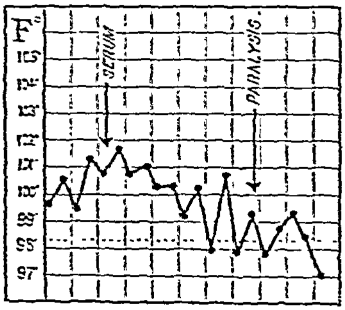
Serum given within 24 hours of paralysis. Satisfactory response.

FIG. 5.



Unsatisfactory response to serum. No second injection was given. Serious paralysis developed.

FIG. 6.



Unsatisfactory response to serum. No second dose was given. Paralysis developed.

STANDARDS OF DISABILITY.

The scheme and standards of the Harvard Infantile Paralysis Commission, as quoted in the article published by Aycock in 1929,[18] were adopted in measuring the degree of paralysis of the cases examined. The scheme may be quoted here:—

> "Five degrees of paralysis are distinguished, depending on the degree of strength shown in the execution of the normal arc of motion with which the particular muscle group is concerned.
>
> "*Good:* muscle is able to perform its function against gravity and some outside resistance.
>
> "*Fair:* muscle is able to perform its function against gravity, but is not able to overcome any outside resistance to the movement.
>
> "*Poor:* muscle is able to perform all or part of its normal arc of movement, but is unable to perform it against gravity.
>
> "*Trace:* no movement is possible, but tendon can be felt to tighten on attempted motion.
>
> "*Gone:* no response can be felt in the muscle or tendon on attempted motion.
>
> "For purposes of tabulation and comparison of different groups of cases, arbitrary numerical values have been assigned to the different degrees of paralysis: good, 1: fair, 2; poor, 3: trace, 4: gone, 5. Muscle examination consists in tests of 106 separate muscle groups, only a few, such as palatal or facial muscles, not being subject to test for degree of paralysis. Paralysis of these muscle groups is uniformly designated as 1. According to this system of grading, complete paralysis of all the muscle groups which are tested would be represented by the figure 530 (106 muscle groups × 5). The numerical values assigned to the different degrees of paralysis do not necessarily represent the actual degree of disability, since a complete paralysis of certain minor groups may not cause as much disability as a partial paralysis of more important groups. However, it comprises a uniform method, and in so far as the number of muscle groups involved and the degree of paralysis are concerned, it is regarded as fairly accurate."

ASSESSMENT OF RESULTS.

In July and August, 1931, muscle examinations were carried out on 88 preparalytic serum-treated cases and 137 of the remainder. The delay between the onset of the disease and muscle examination favoured the controls, for the interval between onset and test averaged 8·5 weeks for the treated cases and their last contribution to the Central Council intimated that the trustees would not be disposed to continue their grants when the L.C.C. had fully developed its powers under the Local Government Act.

Upon the Central Council has fallen the duty of revising and republishing the directory of district nursing and street list for London; the 1918 edition of the directory is now out of date and its value as a reference book makes republication especially desirable from the point of view of hospital almoners, social workers, and general practitioners in the poorer districts of London. It also falls to the Central Council to award bursaries for midwifery training, to which purpose a grant from the London Parochial Charities is directed. Since this special contribution was first made, 36 nurses have been enabled to obtain the C.M.B. certificate. The desirability of extending these bursaries to cover post-certificate courses has recently been discussed, and it has been agreed that applications should be considered for such part of the cost of post-certificate courses as is not met by the Ministry of Health, provided that the candidate will agree to undertake midwifery in London for not less than a year.

A simplification of statistics and accounts is likely to follow the issue of a standard form by the Central Council for circulation among the bodies which come under its organisation. The different modes of presenting income and expenditure accounts made comparison, and the allocation of equitable grants, extremely difficult, and the issue of a standard form is another example of administrative value of the Central Council. District nursing, as Dr. Hogarth pointed out, calls for altruism and a high conception of service in the woman who takes it up, and such devotion, she believes, should not be exploited, even in the interest of the general public. THE LANCET Commission on Nursing noted the valiant efforts of the Nursing Association to obtain funds, and the manifest need for the services of district nurses, but stated their conviction that the pay offered in this field is inadequate. It is to be hoped that these views will receive full recognition in any scheme for reconstruction of the district nursing system.

A SURVEY OF EPIDEMIC ENCEPHALITIS.

THE second report [1] of the Matheson Commission for the study of Epidemic Encephalitis, which has just appeared, is arranged on the same plan as the first,[2] but on a more modest scale. Of its 155 pages considerably more than half are devoted to a continuation of the bibliography of the subject up to the end of 1929. This part of the report should be of great value for purposes of reference. The remainder consists of brief résumés of recent communications grouped under the headings Ætiology, Other Types of Encephalitis, Treatment and Epidemiology. In the second of these is given a table of incidence of post-vaccinal encephalitis in different countries, so far as figures have been available for the purpose. The chapter on treatment aims at recording every drug that has been tried, however rarely or unsuccessfully. Many of the entries might have been omitted without material loss; they serve, however, to indicate the pitfalls of drug treatment in a disease so little amenable to drugs at all. The final chapter contains a brief account of the outbreak of the disease in Japan in 1929. So far the Matheson Commission has limited its reports to the collation and the review of outside work. Since the summer of 1929 however it has been actively engaged in working on material provided at the Columbia University neurological institute, where more than 500 patients, adults and children, have been studied in relation to their response to the vaccines of Rosenow, Levaditi, and Gay. The results, to be published later, will be awaited with interest.

MEDICAL CARE IN INDUSTRY.

A PAPER on the Medical Care of Workers in Industry was read by Dr. N. Howard Mummery to the Epidemiological Section of the Royal Society of Medicine on Friday, Jan. 22nd. The worker, said Dr. Mummery, is to-day so carefully safeguarded that he is in danger of losing his independence and his foresight for himself and his family, and this largely at the expense of the employer of his labour, who is being held responsible for every loss of health, whether due to the employment of the worker or not. The employer is being helped by the Industrial Health Research Board, by the Home Office, and others, but wants good practitioners to assist him in the choice of his workmen in their vocationa selection, in preventing disease by better hygiene in reducing absenteeism, and increasing output. I this work the large factories already employ ove 1000 doctors and 2000 nurses, working under thei direction. Where Dr. Mummery works absenteeis decreases, he said, from year to year; there are 332 men, 1461 women, and in 1930 there were 1564 mal absentees from accidents and illnesses, 1601 femal —a higher proportion of women—but the men we longer absent, averaging 14·12 days, the women 11·0 There was most absenteeism in January, but aft that in summer months. Accidents and illness in frequency varied together; the reduction, ye by year, he ascribed to better immediate treatment injuries, good provision of hospital and convalesce treatment when required. The most numerous cla of illnesses were colds and influenza. Dr. Mumme appealed to practitioners increasingly to devote the attention to the interesting work of assisting industr

BY an Order of the Committee of Privy Counc Mr. W. S. Morrison, M.P., has been appointed member of the Medical Research Council on t retirement of Major A. G. Church.

Dr. W. G. Savage has accepted an invitation to to Boston to deliver the Sedgwick memorial lectu for 1932. He is the first Englishman to hold th lectureship in the nine years since its foundation.

Prof. Grey Turner's address on the Paget Traditio to which we alluded last week (p. 468), was deliver on the occasion of the centenary meeting of t Massachusetts Medical Society. The Bigelow med was awarded him by the Boston Surgical Societ and the lecture he gave on that occasion was entitl Some Experiences in the Surgery of the Œsophagu

POLIOMYELO-ENCEPHALITIS

IN VICTORIA (1925–1931).

REATMENT BY HUMAN IMMUNE SERUM.

BY JEAN MACNAMARA, M.D. MELB.,
MEDICAL OFFICER TO THE PHYSIOTHERAPY DEPARTMENT,
CHILDREN'S HOSPITAL, MELBOURNE; CONSULTANT TO
THE VICTORIAN COMMITTEE FOR POLIOMYELITIS,
APRIL, 1925, TO AUGUST, 1931;

AND

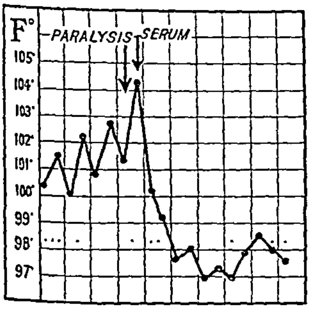
F. G. MORGAN, M.B. MELB.,
ECTOR, LABORATORIES DIVISION, COMMONWEALTH DEPARTMENT
OF HEALTH, AUSTRALIA.

(Concluded from p. 472.)

Results of Serum Therapy.

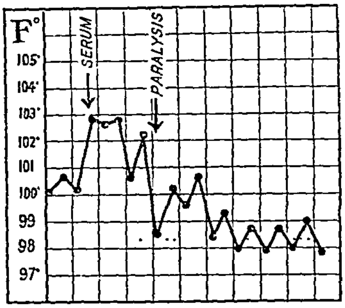
)URING the period under review serum has been ninistered to 260 patients. When a patient has ght treatment within 24 hours of the advent of alysis, if fever persisted an intravenous injection 40–60 c.cm. of serum has been given. The usual not invariable sequence has been an immediate of temperature and arrest of paralysis at the ge existing when the injection was made (Fig 4).)uring the months November, 1930, to July, 1931, epidemic of 270 cases occurred. This excited at public interest. In Melbourne, where most the cases were, families are not large; children valuable. The press, authorities of schools, dergartens, infant welfare centres and similar anisations, united in impressing upon parents the essity for early diagnosis. Hundreds of children, the slightest evidence of malaise, were taken to eir doctors or to the out-patient departments of blic hospitals because the parents feared paralysis. ie general practitioners, many of whom had seen ses in previous years, had special lectures and monstrations, and watched every patient suffering om indefinite illness very closely for the development a spine sign or other warning symptoms. While is possible that a few cases were missed, the widespread interest of public and profession makes one nfident that the number of sick children not tended by a member of the profession during that riod was negligible.

FIG. 4.



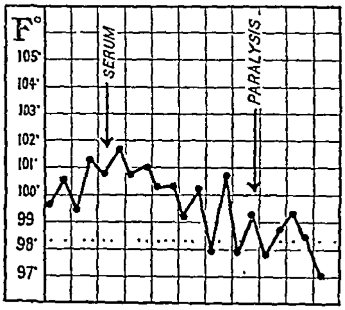
Serum given within 24 hours of paralysis. Satisfactory response.

FIG. 5.



Unsatisfactory response to serum. No second injection was given. Serious paralysis developed.

FIG. 6.



Unsatisfactory response to serum. No second dose was given. Paralysis developed.

It is admitted that the only accurate method to ssess the results of any therapy in preparalytic oliomyelitis would be the treatment of alternate cases, leaving the remainder as controls. In Australia this could not be done. Of the 270 cases of the epidemic, 254 were seen by one of us (J. M.), who was responsible for the after-treatment of the majority of paralysed cases by means of splinting and muscle re-education. It appeared, therefore, that an opportunity was presented to compare the cases treated with serum in the preparalytic stage with the remainder of the cases of the same epidemic.

STANDARDS OF DISABILITY.

The scheme and standards of the Harvard Infantile Paralysis Commission, as quoted in the article published by Aycock in 1929,[18] were adopted in measuring the degree of paralysis of the cases examined. The scheme may be quoted here:—

> "Five degrees of paralysis are distinguished, depending on the degree of strength shown in the execution of the normal arc of motion with which the particular muscle group is concerned.
>
> "*Good:* muscle is able to perform its function against gravity and some outside resistance.
>
> "*Fair:* muscle is able to perform its function against gravity, but is not able to overcome any outside resistance to the movement.
>
> "*Poor:* muscle is able to perform all or part of its normal arc of movement, but is unable to perform it against gravity.
>
> "*Trace:* no movement is possible, but tendon can be felt to tighten on attempted motion.
>
> "*Gone:* no response can be felt in the muscle or tendon on attempted motion.
>
> "For purposes of tabulation and comparison of different groups of cases, arbitrary numerical values have been assigned to the different degrees of paralysis: good, 1; fair, 2; poor, 3; trace, 4; gone, 5. Muscle examination consists in tests of 106 separate muscle groups, only a few, such as palatal or facial muscles, not being subject to test for degree of paralysis. Paralysis of these muscle groups is uniformly designated as 1. According to this system of grading, complete paralysis of all the muscle groups which are tested would be represented by the figure 530 (106 muscle groups × 5). The numerical values assigned to the different degrees of paralysis do not necessarily represent the actual degree of disability, since a complete paralysis of certain minor groups may not cause as much disability as a partial paralysis of more important groups. However, it comprises a uniform method, and in so far as the number of muscle groups involved and the degree of paralysis are concerned, it is regarded as fairly accurate."

ASSESSMENT OF RESULTS.

In July and August, 1931, muscle examinations were carried out on 88 preparalytic serum-treated cases and 137 of the remainder. The delay between the onset of the disease and muscle examination favoured the controls, for the interval between onset and test averaged 8·5 weeks for the treated cases and

plete series of treated cases, 1925–1931. Number 133.						Total muscle examinations (132)								653	183	104	108	68
						Average paralysis per case								4·9	1·39	0·78	0·8	0·5

weeks for the remainder. During that interval entical after-treatment had been carried out in the ralysed cases of both groups. Of 254 cases seen y one of us, 12 apparently successful preparalytic rum cases must be omitted from the series because ridence is incomplete; contamination of the cerebro-inal fluid by blood prevented an accurate cell count. ifteen paralysed cases of moderate and severe egree must be omitted because examinations accord-ig to this method could not be undertaken. The omparison is therefore between 76 cases treated by erum in the preparalytic stage and 151 others, hile the condition of an additional 27 is known. The survey, therefore, may be regarded as representative of the total case incidence of 270 cases. Details of the histories of cases treated in the preparalytic stage during this epidemic are shown in Table III. (Cases 58–133). Limitation of space prevents printing of the results of muscle examination in the complete series of untreated cases; but the records of 25 of these cases are given as a sample in Table IV., together with the summation of the findings for the complete series of untreated cases.

The comparison of degree and extent of paralysis in treated and untreated cases during the epidemic of 1930–1931 is shown in Table V.

TABLE V.—*Comparison of Treated and Untreated Cases.*

Nov., 1930, to July, 1931.	Number.	Death.	Paralysis.					
			Total.	Good.	Fair.	Poor.	Trace.	Gone.
Untreated cases	151	14	6125	1125	1127	1389	1124	1360
Treated cases	76	0	266	133	66	33	24	20
Average paralysis per survivor, November, 1930, to July, 1931—								
Untreated cases ..	137	—	45·4	8·2	8·2	10·1	8 9	9·9
Treated cases	76	—	3·5	1·7	0·8	0·4	0·3	0·2
Complete series of treated cases, 1925–1931.. ..	133	1	653	183	104	108	68	190
Average paralysis per survivor	132	—	4 9	1·39	0·78	0·8	0·5	1·42

The prognosis for ultimate recovery of function depends upon the number of muscle groups affected to the degree connoted by the standards: poor (3), trace (4), or absent (5). If all paralyses could be classified as grades (1) good, and (2) fair, poliomyelitis would lose its terror; for muscles paralysed to either of these grades achieve recovery if after-treatment be carried out. When muscles are affected to the grades trace (4) or absent (5) recovery rarely occurs; and in those paralysed to the third degree (poor) recovery necessitates years of careful after-treatment.

Table VI. compares the treated and untreated cases from this aspect of the incidence of severe paralysis with its sequelæ of permanent crippling and loss of economic independence.

TABLE VI.

—	No.	Deaths.	No. with paralysis of Grades 3, 4, and 5.	Percentage of survivors affected in Grades 3, 4, and 5.	Case No.	Grades—		
						3 Poor.	4 Trace.	5 Absent.
Treated cases	76	0	4	5·2	91 111 114 118	9 12 6 6	0 24 0 0	0 16 0 5
Untreated cases	151	14	88	58·2	Aver. per survivor	15·7	12·7	15 4

Failures.

Of the complete series treated (133), seven must be regarded as failures—No. 20 (the fatal case), and Numbers 6, 10, 41, 111, and 118. Cases 6, 10, 41, and 20 shared one common feature in their history—namely, *delay* between withdrawal of a large quantity of cerebro-spinal fluid and administration of serum. With one exception (Number 47) they are the only cases in which this delay occurred. In the others, examination of the fluid has been made forthwith and serum administered within one hour of lumbar puncture. It is suggested that the failure of these cases may be due to one or both of two factors: (1) delay, elapse of hours allowing death of cells to occur before passive immunity was induced; and (2) that the actual withdrawal of large quantities of cerebro-spinal fluid during the preparalytic stage may have actually determined involvement of the cord.[15]

Case 48 was given one injection of serum—30 c.cm. intramuscularly on the third day of her illness—and although the temperature did not fall, no second dose was given. Her paralysis confirmed the lesson taught by a small series of cases treated in Tasmania with Victorian serum, that 30 c.cm. is usually an inadequate dose. The temperature charts of Cases 111 and 118 reveal the explanation for their failures (Figs. 5 and 6).

To Case 111, through confusion with cerebro-spinal meningitis, and to Case 118, through an oversight in the rush of the epidemic, no second injection was given, though the response to the first was not satisfactory. These failures, together with the paresis, which, although clearing up rapidly and completely, could be demonstrated in 60 other treated cases, proved beyond question that of the total series of 133 cases diagnosed and treated before paralysis, 66 were actually cases of poliomyelitis. The remainder, who developed no paralysis, presented the same clinical picture as this group of 66. Moreover, no other disease developed subsequently to suggest any other diagnosis for the signs and symptoms presented.

Conclusions.

1. It has been possible to diagnose poliomyelitis as manifested in Victoria between 1925–1931 in the preparalytic stage.
2. The use of human immune serum at this stage, in adequate dosage, has given excellent results as evidenced by a low mortality-rate, a low average total paralysis, and a strikingly low proportion of paralysis of the severer grades (as has been reported in 1929 by Aycock[18]).
3. Delay between withdrawal of cerebro-spinal fluid for examination and the administration of serum is to be avoided.
4. The dosage required is variable, and a second injection should be given if the response to the first is not prompt and satisfactory.
5. It is advantageous that the serum used should be free from any substances which provoke reactions.
6. The viricidal properties of the serum available for use should be repeatedly tested by inoculation of monkeys against specimens of virus obtained in different epidemics.
7. If supplies are ample, administration of serum within 24 hours of the development of paralysis to a febrile patient is justified, and is usually followed by a fall of temperature and arrest of paralysis.
8. If given later, when paralysis is stationary, serum is of no value.
9. In the "ascending" group of cases (Landry's paralysis) the administration of serum is justifiable, but there is no certainty that the spread of paralysis will be arrested.[19]
10. Adequate after-care of all potential donors—paralysed adults and children over the age of 10—in the intervals between epidemics, and personal practical interest in their struggle for recovery is the crux of any scheme for provision of serum stocks in an emergency. By these means the store of immune human serum has been adequate to all demands of Victoria and Tasmania during the six-year period.

We acknowledge our indebtedness to the medical profession of Victoria, whose generous coöperation has made this work possible; to the Director-General of Health of the Commonwealth, Dr. J. H. L. Cumpston; to the advisory committee, Prof. Peter McCallum, Drs. C. H. Kellaway, R. Webster, F. V. Scholes, F. M. Burnet, who shared the responsibility of the earlier years; to the Poliomyelitis Committee of Victoria for financial administration; to Mr. Morrell and Miss May Kennedy, of the staff of the laboratories. We would thank the honorary medical staff of the Children's Hospital, Melbourne, for facilities granted at the hospital: the staff of the physiotherapy department and the resident medical officers for continued help in tedious detail, and especially the superintendent, Dr. Ian Jeffries Wood, for his enthusiasm and painstaking care during the epidemic of 1931.

THE LANCET COMMISSION ON NURSING.

(Continued from p. 475.)

THE table of contents of the Final Report[1] of thi Commission, which was published in THE LANCE of Feb. 20th, showed that the extent and the natur of the shortage of candidates for the nursing profession is carefully examined in Section IV., and th main reasons for the shortage is discussed in Section V under the following headings: (*a*) The Gap betwee School and Hospital; (*b*) Pay and Prospects (*c*) Hours of Work; (*d*) Conditions of Admission an Service; (*e*) Professional Education. The reason for the shortage of trained staff are examined an discussed in Sections VI. and VII. Section VII is devoted to the staffing of non-approved hospital and Sections IX. and X. respectively to the speci difficulties of tuberculosis and mental hospitals. I Sections XI. and XII. the Commission revert t some controversial aspects of the general problen Section XI. is set out in full below.

Some Questions of Policy.

Certain proposals to which allusion has already been made[2] demand brief notice. These concern the advisability of:—

(*a*) Establishment of schools of nursing connected with universities.
(*b*) Replacement of five registers by one register.
(*c*) Substantial shortening of courses of training.
(*d*) Official recognition of two grades of nurses.
(*e*) Propaganda.

Most of these issues are outside our terms of reference. Changes as fundamental as (*a*), (*b*), (*c*), and (*d*) would involve considerations other than the relief of a shortage of candidates, and could not properly be urged solely with a view to relieving such shortage. Since, however, considerable stress has been laid on one or other of these proposals in some of the evidence submitted to us, it seems desirable to outline our reasons for making no recommendations on them.

ESTABLISHMENT OF SCHOOLS OF NURSING CONNECTED WITH UNIVERSITIES.

Nursing is essentially a craft, and as such is inseparable from the material on which it is exercised. While the endowment of schools of nursing is highly desirable (see para. 120), it can be argued that in order to maintain the practical quality which has distinguished British nursing, such schools should be attached to hospitals rather than to academic institutions of university status.

Certain members of the nursing profession specialise in branches such as administration, teaching, and dietetics, and training in such branches may be a function of a university. Diplomas in nursing for which only trained nurses are eligible are available in the universities of London and Leeds. In Leeds attendance at a three-months' course of lectures is required; in London the diploma is not an "academic" diploma—i.e., the nurse who has had the requisite experience can sit for the examination without having attended any special course. It is probable that there will be an increased demand for such diplomas in the future.

A SIMPLER FORM OF REGISTRATION.

The institution of one register with supplementary diplomas may be desirable when our hospital system is more unified, but the recruitment of nurses, particularly for the special hospitals, would not be furthered by a reorganisation of this kind at the present time. It is obvious that if a less complicated system of registration had been considered possible 12 years ago, it would have been adopted. The reasons against a simpler system which applied in 1919 are no less valid to-day. The introduction of more than one register was a measure designed to help the mental, fever, and children's hospitals to enlist probationers by offering them State recognition, and though one of these groups (mental hospitals) has taken little advantage of the opportunity offered (see para. 321), the removal of such opportunity would make it less rather than more easy for special hospitals to provide nursing care for their patients.

From the point of view of recruitment alone, it might be desirable not to abolish the Supplementary registers, but to raise the prestige of nurses on these registers by enabling them to qualify for inclusion in the General register after short additional courses. At the present time the regulations of the General Nursing Council permit nurses whose names are on any Supplementary register to be admitted to the general part of the register after only two years' training in an approved complete training school; but few such schools are willing to accept nurses on these terms, and in practice a registered mental, fever, or children's nurse usually has to start afresh as a probationer and work for three years before admission to the General register.

Widespread coöperation between different hospitals, or groups of hospitals, seems a goal unlikely to be reached in the near future for reasons quite unconnected with nursing. The fact that the voluntary hospitals of the country are separate autonomous institutions, competing with each other for support from the charitable public, and jealous of their reputations as training schools for nurses, places difficulties in the way of coöperative training. The organisation of combined training courses of reasonable length at municipal hospitals might be less formidable, since mental and fever hospitals are for the most part under Local Authorities. Few girls, however, would be willing to bind themselves to a course of training lasting for more than four years; while general hospitals would hardly agree to shorten the part of the training taken in those hospitals sufficiently to enable much time to be spent in mental, fever, or children's hospitals.

The registers are never likely to be reduced to less than three in number. The qualities and experience needed for mental nursing differ from those needed in general nursing, and a separate register for mental nurses will probably always be desirable; while a separate register for male nurses is convenient. The Supplementary parts of the register for those trained respectively in the nursing of infectious diseases and in the nursing of children come into a different category, but we do not at the present time recommend their abolition.

SUBSTANTIAL SHORTENING OF COURSES OF TRAINING

The substantial shortening of the course of training —i.e., to two years and four months—was recommended by the Rockefeller Committee in America,[3] but the proposal found little favour in that country, nor would it be likely to receive support in Great Britain. The leaders of the nursing profession in this country point to the large number of departments in which the nurse must gain experience, as a reason why no substantial shortening of the course could be contemplated. It would obviously be necessary to allocate nurse students to posts for two instead of for the usual three months in the wards and special departments, if all-round experience were to be gained, but they consider it doubtful whether a shorter experience would be sufficient to give any but the exceptional girl an insight into her duties. Those who advocate a shortened course argue that an educated woman could gain the necessary theoretical grounding, and learn nursing procedure in every branch of her work, in a shorter time than three years, provided that she was relieved of domestic work once she had become proficient in it. They hold that if the nurse is taught fundamental principles —e.g., asepsis, the avoidance of shock, the care of the skin—she should be able to apply these principles in all branches of her work without long experience in each department.

The prospect of shorter training might well attract some girls, especially those who desire ultimately to go into other branches of nursing and do not care to contemplate three years of institutional life; but there would be the disadvantage from the point of view of the hospitals that the institutions would benefit from the services of each probationer only over a shorter period. From the point of view of the rising generation of nurses the shortened training, with a bigger turnover, might bring the risk of overcrowding in the profession. There seems, however, to be little advantage in discussing in detail arguments for and against a substantial shortening of a three-year course, because though the proposal might be welcomed by prospective candidates, it is not likely to be acceptable either to the nursing profession or to the hospitals.

GRADING.

We are aware of a widespread feeling among the public and among a certain section of the medical profession that the training of a nurse at present is much too elaborate and that, at least for chronic cases, a less highly equipped attendant would serve. The recognition by registration of two grades of nurses would, it is said, bring back into the profession those who have a real vocation, but whose lack of previous education, or incapacity for book-work, unfits them to pass the examinations now required of every State-registered nurse. The opponents of grading base their arguments on its dangers to (1) the nursing profession and (2) the public. They point out that the hard-won professional status of a nurse would be endangered thereby and that her economic position would also suffer, since, in private work at least, a second-grade nurse would be likely to undercut her. In this way the introduction of grading might, it is held, prejudice recruitment of the best type of girl to the profession. The danger to the public would be that a second-grade nurse might be entrusted, through ignorance of her limitations or for economic reasons, with responsibilities which she had not been trained to fulfil, and disastrous results might ensue. The strong feeling in the nursing profession that women trained for a shorter time on a much modified syllabus should not be allowed to use the honoured title of "hospital nurse" can readily be understood. That there is room, especially in hospitals not approved for training, for attendants who could attend to the physical needs of the patients and make them comfortable under the supervision of a trained nurse, is probable. It is probable also that such attendants would be appreciated in homes where help is required with chronic invalids. But the conditions of their employment on a large scale, and the methods of safeguarding the State-registered nurse, are matters which would require much consideration.

PROPAGANDA.

It has been urged upon us that some more systematic propaganda on the needs and attractions of the nursing profession is required. Evidence that the attention of girls has not been sufficiently directed to this profession has reached us from many sources. The circulation in schools of interesting and attractively printed pamphlets, the display of notices explaining the openings and methods of entering the profession, and the arrangement of visits to hospitals, would doubtless stimulate recruitment. The insertion of advertisements in journals read by girls of the age and type it is desired to enlist, the provision of lectures and the production of films illustrating the training and career of hospital nurses would also be of value.

jection shounropaganda of this kind would, however,
not prompt and satisfact the developments, to the

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

THE GLASGOW HOSPITALS.

EACH of the three great general hospitals of Glasgow—the Royal, the Western, and the Victoria Infirmaries—reports a heavy excess of expenditure over income in 1931. On ordinary expenditure the Royal had a deficit of £24,200, the Western of £12,500, and the Victoria of over £20,000. The position of the Royal Infirmary is especially unhappy, notwithstanding that it is managed so economically that the average annual cost per occupied bed is £120 17s. 6d., as compared with the £177 spent in "one of the largest hospitals in England outside London." The in-patients are always in excess of the recognised bed state, which is a little under 800. Yet the average last year was a fraction over that figure, and the number has been as high as 870. Ordinary subscriptions and donations from employees fell by £5200, and there is no immediate prospect of improvement in this respect. The working deficiency was made up out of legacies which aggregated £47,000. As with practically every other hospital, road-accident cases helped to strain resources both in beds and money. There were 541 such cases under treatment for 8766 days at a cost of £3287, of which only £826 was recovered from the insurance companies. Among recent developments at the Royal Infirmary are a massage school for male students, and a medical gymnasium which has not only been of service to massage pupils but to the orthopædic department. It is now possible to give medical gymnastics and remedial exercises to patients in groups, instead o taking each individually. The hospital is negotiatin for a supply of radium from the Commission, but th quantity is expected to be small.

Although the Western Infirmary also worked a a loss last year its report is, on the whole, mor cheerful reading. At £70,780 its income was less b £3594, again as the result of unemployment; th expenditure was £83,300, but, taking legacies int account, receipts exceeded expenditure by nearl £7000. There is not the overcrowding which add so greatly to the difficulties of the Royal. Th average daily number of patients was 587, a little le than the bed capacity. The average stay was 17· days, and the average cost per patient £6 9s. 3 an increase of a few pence; the daily cost was 7s. 7 There was an abundant supply of aspirant prob tioners, 594 applications having been received. The new ophthalmological department is now being proceeded with; the new radiological department, which has now been at work for a full year, is of great value, and the demands upon it are continually increasing. The hospital, which is the National Radium Centre for Glasgow, is receiving an increasing number of cancer cases from most parts of Scotland, and "the results in the cases of malignant disease suitable for radiation therapy are regarded as satisfactory."

Last year the Victoria Infirmary exceeded all previous figures in the number of its in-patients, which increased by 1136 to 8616. This was partly accounted for by the 448 persons treated in the paying patients' annexe which has been fully occupied since it was opened in April last. The waiting-list for the free beds is usually about 400. There were 217 in-patients and 317 out-patients suffering from motor accidents; £600 was received from the insurance companies. The ordinary income was £51,343, and he ordinary expenditure £71,816. and after various djustments the net deficit of £14.940 was drawn rom capital account.

THE TEACHERS OF MENTAL DEFECTIVES.

The Scottish Education Department has decided o shorten the course for teachers of mentally defective hildren from six months to three months. At present the teaching is conducted at Jordanhill Training Centre, Glasgow. By rearranging and ntensifying the instruction, the National Committee or the Training of Teachers have provided a course which, it is believed, will be as effective as the longer one. The cost of the special training will thus be reduced. It will be possible to provide a larger supply of qualified teachers for the mentally defective. At present there is a shortage. The teaching of mental tests has been elaborated in very specialised ways. and careful training of the teachers is essential if their opinion of an "intelligence quotient" is to be worth anything. On the other hand. as Prof. Cyril Burt long ago pointed out, a good teacher is of more importance than the most refined tests. The fundamental problem is how to distinguish between "backward" and "defective," and once the distinction is made, how to secure them appropriate places in the industrial world. The Scottish National Committee has taken this step after extended consideration.

MATERNITY HOSPITAL DEATH-RATES.

Dr. James Young (Edinburgh), in an address on the Organisation and Administration of Maternity Hospitals, has stated that in the Glasgow Royal Maternity Hospital during 1930 there were 119 deaths in 4469 cases (26·6 per 1000), while in the Edinburgh Royal Maternity Hospital during the same year there were 36 deaths among 2305 patients (15 per 1000). He compared these results with the record of the East End Maternity Hospital in London, which had 8890 births with 10 deaths (1·1 per 1000). He pointed out that these differences were partly due to the fact that in the case of Glasgow and Edinburgh institutions there was a high concentration of abnormal and difficult maternity cases from the large areas which they served. This. however, did not explain everything, because a comparison of the same class of case showed that in the hospital in the poor quarter of London there had been 200 cases of the toxæmias of pregnancy with no deaths, whereas in Glasgow there had been 448 such cases with 22 deaths (4·9 per cent.) and in Edinburgh 17 out of 208 cases (8·1 per cent.). The same facts were revealed in regard to a comparison of other types of complications. Dr. Young pointed out that the high death-rate in the Scottish hospitals arose from factors over which they had little control. The patients arrived at the hospital with their health and chances already jeopardised. In other words, the hospitals were handicapped in so far as the cases arrived often in such a state that little could be done. The lesson to be drawn from these comparisons was that when the domestic midwifery service and the service for the supervision of pregnancy were sound, the hospital death-rate was small. When it was inferior, this death-rate was high. The inference was that there was urgent need for a revision of our maternity methods. Another fact of importance was that our central hospitals admitted patients who were "suspect" in the sense that they had suffered damage before their admission. This class of case endangered the normal healthy women, because they were so apt to be infective. To meet this risk, the modern hospital must have a system by which the two classes of cases were rigidly segregated from one another in separate buildings under a separate staff.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

MEDICINE IN THE NEW DÁIL.

MEDICINE is represented in the new Dáil by eight members. Mr. G. Hennessy, Dr. Myles Keogh, and Dr. T. Higgins retain their seats as members of the Cumann na nGaedheal Party; Sir James Craig has again been returned as an Independent; Dr. J. Ryan and Dr. F. Ward have held their places in the Fianna Fail Party, and they have been joined by two newcomers, Dr. J. B. Lynch and Dr. F. Humphrys. Two former members of the Fianna Fail Party. Dr. P. J. O'Dowd and Dr. J. A. Tubridy, failed to secure re-election. The total number of medical men in the Dáil is therefore the same as before.

Speculation is busy as to the effect on medical affairs of the change of Government which will take place next week. It is recognised that the outgoing Government has a good record in regard to health legislation. During their ten years of office a system of public health administration has been established. and there has been radical improvement in the condition of the local hospitals. The reforms in local administration have led to increased efficiency, and the work of the Appointments Commission is gradually improving the quality of entrants to the public medical service. A good deal remains to be done, however, for Ireland still lags behind neighbouring countries in many matters concerning health. It is hoped that the incoming Government may adopt a vigorous health policy as a line of action which would cause little strenuous opposition, and therefore be safe for a Government which rests on a narrow majority to pursue. The influence of the Labour Party, which is bound to be considerable, may be relied on to be used in this direction. Already the leaders of that party are insisting that a national housing scheme must be one of the earliest activities of the new Government. It is probable that medical treatment for insured persons and the conversion of the public medical services into a national medical service will also have the support of the Labour Party.

PRESENTATION TO PROF. SINCLAIR.

In the Great Hall of the Queen's University of Belfast on Feb. 16th a tribute of affection was paid to Prof. Thomas Sinclair when he was presented with his portrait in oils, painted by Mr. George Harcourt. R.A. Viscount Bangor presided over a large company of Prof. Sinclair's medical colleagues, former pupils, and personal friends. Sir Thomas Houston. in asking the Recorder of Belfast to make the presentation, referred to the great work which Prof. Sinclair did for the Belfast Medical School during the 37 years he occupied the chair of surgery, and which entitled him to be styled the founder of modern surgery in Ulster. In presenting the portrait Judge Thompson said that hundreds of people had been eager to be associated in this permanent memorial. The portrait will hang in the Great Hall in the years to come, for Prof. Sinclair on receiving the gift presented it to the University, and it was accepted by the Vice-Chancellor as a portrait of a beloved and honoured alumnus as well as a notable work of art. It will appear in London at this year's exhibition of the Royal Academy.

UNITED STATES OF AMERICA.

(FROM OUR OWN CORRESPONDENT.)

AUTOMOBILE ACCIDENTS IN 1931.

An impressive summation of facts and figures regarding the automobile accidents of last year is presented by the Travellers Insurance Co., of Hartford, Conn., in a brochure. The growth of automobile fatalities is shown in five-year periods; 58,552 for the period ending 1921, 98,551 for the period ending 1926, 152,732 for the period ending last year, and a row of alarmingly large question marks for the period ending 1936. These deaths are then analysed in a number of interesting ways and the accidents are described and illustrated by photographs and diagrams. One excellent photograph strikingly proves how much more visible is a pedestrian facing the headlights than the same man at the same distance, but with his back to the headlights. The exercise of personal responsibility is regarded as the fundamental prerequisite to accident prevention, and these striking illustrations, one of which shows the total of deaths and injuries from automobiles last year (1,032,000) in comparison with the populations of Nevada, Delaware, Wyoming, and the District of Columbia (1,042,000), will certainly aid in promoting responsible behaviour. The brochure will be valuable alike to those who are interested in the causes of automobile accidents and those who will prize a fine example of publicity applied to a worthy cause.

UNEMPLOYMENT AND MALNUTRITION.

When inaugurating a new service of wireless health talks from Baltimore recently, Dr. W. H. Welch referred to "the unavoidable curtailment of available funds" which "places a severe strain upon efficient administration of our city health department," and added these words:

> A very important consideration in these unpredecented days of unemployment is that health and vitality are directly related to means of subsistence and standards of living, especially in the case of infants and children. Every effort should be made to guard against permanent and irremediable damage to health and strength as a legacy of the hard times through which we are passing.

All through the country we find evidence that official health authorities and voluntary organisations are awake to the dangers enunciated by Dr. Welch. An article on Emergency Nutrition by Prof. Henry C. Sherman, of Columbia University, has appeared in the *Child Health Bulletin*, has been given the advantage of partial reprinting in the *Literary Digest*, and with other information of the same kind may now be had from the American Child Health Association (450, Seventh-avenue, New York). Pamphlets have also been prepared by the Bureau of Home Economics (U.S. Department of Agriculture, Washington, D.C.), and will have wide circulation through the county agricultural agents scattered over the vast rural areas of the United States. Add to this publicity the feature stories supplied to newspapers and the special publications of the State health departments, and it is evident that an effective campaign is being waged to prevent malnutrition in the United States.

FERTILITY OF NATIVE WHITE AMERICANS.

Working for the Milbank Memorial Fund's division of research Edgar Sydenstricker,[1] the eminent statistician, writes on the fertility of native white women in a rural area of Western New York. The area includes five townships in Cattaraugus county, with a total population of about 5000, composed almost entirely of native white families of the "older native stock." To 1036 women who had been married only once and had not been permanently separated from their husbands before their forty-fifth birthday, there had been born 2959 live children. The average number of children per wife is thus 2·86. The average of course increases with age from just over one child at age 25 to an average of 3·31 for women aged 45 and over. Yet more than a quarter of the mothers in this group had born either no children at all or only one child. The average, Sydenstricker concludes, is probably sufficient to maintain the size of a relatively healthy rural population. Dividing the rural women into three groups according to the occupation of the husband—farm, labour, or business—and standardising the birth-rate for age, it was found that fertility-rates vary with occupation even in a rural community, the highest rate (2·99) being found in the farm group, and the lowest (1·89) in the business group. The size of the sample for this purpose is small, and the relative fertilities of these groups cannot be accurately gauged by the above figures. But it seems clear that there is an occupational influence. It is of interest too that this occupational difference becomes emphasised with the length of married life, and appears scarcely at all in the first three years of marriage. There is thus no indication that the business group is pressed to use contraceptive methods in early married life by economic considerations. In comparing the fertility-rates in this area for 1929–30 with those of 1910 and 1920 it is found that there has been no significant downward trend in the fertility-rate of farmers of native white stock. Is the general decline of fertility in our "older native stock" a matter not of "lessened vitality" but rather of changing environment? Such are the interesting speculations which this research has aroused.

MEDICAL RESEARCH COUNCIL.

ANNUAL REPORT FOR 1930–31.[1]

In presenting the Report for 1930–31 of th Committee of the Privy Council for Medical Researc Mr. Stanley Baldwin, as Lord President of Counci draws special attention to the appointment in Jul 1931, of the Agricultural Research Council. I Charter of Incorporation is closely similar to that the Medical Research Council, appointed 12 years ag and coöperation between the two bodies will be assu by the provision that they will have at least o member in common. He mentions the laws nutritional science and the methods and results which they can be elucidated, and the study disease in the animal kingdom, among the found tions on which both agriculture and medicine ba their powers.

VITAMIN D.

The Report of the Medical Research Coun records fruitful and encouraging results of the yea work. Foremost among these is placed the attai ment of accurate knowledge of vitamin D. in ter of its chemical structure and physical properties. The importance of possessing a fixed stable substance by reference to which the vitamin D activity of any foodstuff or remedy can be measured, need hardly be emphasised. A standard preparation of the parent substance, irradiated ergosterol, is already maintained at the National Institute for Medical Research for international reference. The wisdom of le provision made for the redefinition of this inter-tional unit in terms of the pure substance, when this ould be found, is now apparent; for it seems kely that the isolation of calciferol at the National stitute and the practically simultaneous isolation f the same substance (as vitamin D_2) by Prof. . Windaus and his colleagues at Copenhagen, will ulfil this condition. The story of great technical ifficulties successfully overcome by the team of nvestigators under the general leadership of Dr. R. B. ourdillon makes stimulating reading. Practical tudies undertaken to explore the possibilities of xploiting for the public benefit the known biological roperties of this vitamin are also recorded. The onfirmation by a large scale controlled investigation f the view first put forward by Mrs. May Mellanby, n experimental evidence, that the incidence of dental aries in formed teeth might be diminished by the ddition of vitamin D to the diet, is described; he results of an investigation into the effect of giving vitamin D to children whose teeth are in the course of development will be published next year, and are expected to bring out the value of the vitamin to an even more striking degree. It is clear that many dietaries regarded as adequate may not really be so.

VIRUS DISEASES.

The chance of finding and identifying the particles of any specific virus by microscopic methods has been greatly increased by the introduction by Mr. W. J. Elford, Ph.D., of a series of graded collodion membranes for use as filters. The "filterable" viruses are so called because they can pass through porcelain and other finely porous filters that hold back ordinary bacteria; the absolute and relative dimensions of the particles of any virus can only be estimated, however, if a graded series of filters is used, with pores not only smaller than those in porcelain filters, but closely uniform in size in each grade. The use of "gradocol" filters indicates, for example, that the virus particles of infective ectromelia, a disease of mice, have a diameter of between 0·1 and 0·15 μ; the virus particles of any of the three types of foot-and-mouth disease are much more minute—being between 0·008 and 0·012 μ; a bacteriophage for the colon bacillus has a diameter of 0·02 to 0 08μ; and the limits of the filtration of the vaccinia virus through graded membranes have been determined by Dr. C. H. Andrewes and Dr. Elford with sufficient accuracy to justify an estimate that its units have a diameter of 0·125 to 0·175μ. Preliminary trials by Mr. J. E. Barnard, F.R.S., give promise of a successful demonstration of the living virus of vaccinia in ultraviolet photomicrographs.

Viruses affecting the nervous system, the virus of herpes, and the viruses of avian tumours are also being studied.

The common cold.—Reference is made to the success with which Dr. A. R. Dochez, of New York, transmitted the common cold to apes by the use of material derived from persons in the early stages of catarrh, and filtered so as to exclude bacteria. Clear evidence was obtained, and subsequently confirmed with human volunteers, that the causal agent belonged to the virus group; the virus could be cultivated outside the body, and after a series of subcultures, still produced typical catarrh in a susceptible individual. Dr. Andrewes visited this work and it is to be repeated in this country with human volunteers from among the students of St. Bartholomew's Hospital. The fact that only a brief immunity succeeds infection by this catarrhal virus unfortunately diminishes the prospect of any rapid attainment of the means of practical control.

Virus studies and cancer.—The study of the immunity reactions of the viruses producing malignant tumours in fowls has been pursued by Dr. W. E. Gye and Dr. W. J. Purdy, and correlated with the results of work on the immunity reactions of other known viruses. The evidence obtained supports the view that in these tumour filtrates we are dealing with an infective virus which is similar, as regards the immunity reactions it can elicit, to some of the acknowledged viruses causing specific diseases.

RESULTS OF INSULIN TREATMENT.

An inquiry into the results of insulin treatment at special centres is in progress. One series of over a thousand cases under treatment at one centre in the period 1925–31 is now being submitted to statistical analysis. Almost all the patients received insulin, except those cases in the highest age-group which were of the mild and slowly progressive type which can more conveniently be controlled by diet alone. The figures for young and middle-aged subjects show a great preponderance of cases where good health is maintained against all expectations based on previous experience. Moreover, the real gain is much greater than any figures can show, since these cannot measure the contrast between the full measure of bodily and mental vigour now obtained with the ever-increasing and distressing invalidism which was the lot of the diabetic in pre-insulin days.

THE RELATION OF THE COUNCIL TO MANUFACTURING FIRMS.

The Medical Research Council regard it as one of their primary functions not only to promote the stages of scientific discovery as such within the medical field, but also to facilitate the "availability" of the results of discovery in the interests of the public and the medical profession. Often much time and labour must be given before the yield of a new substance can be brought into the phase of large scale production or a new method be adapted for widespread use. Coöperation between investigation and manufacturing firms has been promoted by the Council in various ways, of which one is the organisation of the Therapeutic Trials Committee.[1] This committee works in close touch with the Chemotherapy Committee, who may be responsible for the experimental work with the drugs or preparations submitted that may be necessary or desirable before their use in man. Consultation with the Association of British Chemical Manufacturers has resulted in the formulation of agreed conditions under which new substances may be submitted for clinical study, and certain clinical trials are already in progress. The Medical Research Council regard the improved machinery for assisting the British production of new therapeutic substances as only an added phase of what has been their normal relationship to manufacturing production for many years. The Council assisted by special research the rapid development in the country of manufacturing insulin, and gave assistance by the study of methods for the production of vitamin D, various organic extracts, and material for inoculation against distemper. On the other hand the chief manufacturing firms have always been ready to offer the results of their experience, the supply of raw materials, or help in other forms. Among the names of firms mentioned in this connexion are the British Drug Houses, Lever Bros., Burroughs

---

[1] See THE LANCET, 1931, ii., 301.

Wellcome and Co., Bovril, Ltd., Boots Pure Drug Co., and Parke, Davis and Co., to which firms the Council express grateful acknowledgments.

CERTAIN OTHER INVESTIGATIONS.

The effective concentration of *puerperal fever* cases at one centre (Queen Charlotte's Hospital) and the organised study of the disease by clinicians and laboratory workers in intimate association is in progress. The chances of recovery for each patient are said to be much increased by the proper concentration of special clinical experience, combined with appropriate laboratory work. Of the 200 grave cases received in the first 12 months only 30 died, though the usual death-rate of such cases is much higher.

Status lymphaticus.—The collective investigation of "status lymphaticus" organised in conjunction with the Pathological Society of Great Britain and Ireland, has been completed, and the conclusion has been reached that the statistical results obtained provide "no evidence that so-called 'status thymico-lymphaticus' has any existence as a pathological entity."

Reference is made to the completion of the publication of the volumes of "A System of Bacteriology," and to the support offered by the Council to the new periodical *Nutrition Abstracts and Reviews.*

The case for amendment of the British Patent Law, and the history of the attempts made by the Council to bring their views on this subject to the notice of the Government are outlined and a memorandum submitted to the Departmental Committee on the Patents and Design Acts and Practice of the Patent Office is printed in full as an appendix to the Report.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 20TH, 1932.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 73 (last week 70); scarlet fever, 1516; diphtheria, 994; enteric fever, 25; pneumonia, 2059; puerperal fever, 38; puerperal pyrexia, 103; cerebro-spinal fever, 52; acute poliomyelitis, 6; encephalitis lethargica, 12; dysentery, 26; ophthalmia neonatorum, 106. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Feb. 23rd–24th was as follows: Small-pox, 129 under treatment, 10 under observation (last week 118 and 4 respectively); scarlet fever, 1204; diphtheria, 1524; enteric fever, 9; measles, 1337; whooping-cough, 349; puerperal fever, 17 (plus 14 babies); encephalitis lethargica, 220; poliomyelitis, 4; "other diseases," 205. At St. Margaret's Hospital there were 16 babies with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 65 (21) from measles, 4 (0) from scarlet fever, 67 (11) from whooping-cough, 38 (10) from diphtheria, 57 (15) from diarrhœa and enteritis under two years, and 364 (96) from influenza. The figures in parentheses are those for London itself.

The number of deaths from influenza reported has risen sharply, the fatal cases being distributed fairly evenly over the country. Of the great towns Leicester stands highest with 19 deaths, Sheffield following with 13, Bristol with 11, and Great Yarmouth with 10. The total deaths for the year from influenza so far amount to 2312 against 2083 for the corresponding period of 1931. The fatal case of enteric fever occurred at Watford. Manchester reported 6 deaths from measles, Oldham 5, and West Ham 4. Whooping-cough claimed 13 victims at Birmingham, 7 at Manchester. Liverpool reported 4 deaths from diphtheria.

The number of stillbirths notified during the week was 295 (corresponding to a rate of 42 per 1000 births), including 38 in London.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdr. (D) J. S. F. Horton is placed on the Retd. List with the rank of Surg. Comdr. (D).

The following appts. are notified: Surg. Lt.-Comdr. (D) H. J. Lock to *Rodney*; Surg. Lt. (D) L. F. Fairey to *Sussex*; and Surg. Lt. W. D. M. Sim to *Cambrian*.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Lt. W. Lennon to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Capt. C. Russell to be Maj.

Lt. R. E. Gordon resigns his temp. commn.

M. J. Kohane is granted a temp. commn. in the ra of Lt.

R. D. MacRae to be Lt. (on prob.).

ARMY RESERVE OF OFFICERS.

Lt. L. P. Clarke, R.A.M.C. (T.A.), resigns his commn. the Res. of Off., and retains the rank of Lt.

TERRITORIAL ARMY.

Col. R. E. Bickerton (Hon. Col. 56th (1st Lond.) Di having attained the age limit, retires and retains his ra with permission to wear the prescribed uniform.

Capt. S. Vatcher resigns his commn.

E. G. Gerstenberg (late Offr. Cadet, Glasgow Univ. Cont Sen. Div., O.T.C.) and G. H. Thomson to be Lts.

ROYAL AIR FORCE.

Dental Branch.—The undermentioned relinquish t temporary commissions on return to Army duty: Squad Leader A. A. McMullan, Major, Army Dental Corps, Flight Lt. R. E. Edwards, Captain, Army Dental Corp

DEATHS IN THE SERVICES.

Lt.-Col. John Lawrence Van Geyzel, C.I.E., I.M.S. (re died suddenly at Hotel Beau Lieu, Cannes, on Feb. aged 74. The son of John Abraham Van Geyzel he educated at the Royal Academy at Colombo, Ceylo which city his father lived, and subsequently he gradu at Aberdeen University M.B., C.M. in 1879. In the fo ing year he entered the Indian Medical Service, and later appointed District Medical and Sanitary O holding that office till 1887, when he became Che Examiner to the Government of Madras and Profess Chemistry to the Madras Medical College, a post whi held for 24 years. He then became Examiner of M Stores to the India Office. Lt.-Col. Van Geyzel was a F of Madras University. He married Catherine daughter of Mr. W. J. Palmer, of Hertford, by who had four daughters.

New Midland Hospitals.—The two citie Coventry and Lichfield, so long joined togethe one diocese, are simultaneously intending to erect hospitals. Coventry is about to build an infe hospital at a cost of £123,500, less £65,000 for the city council has sold the existing building to the Cov and Warwickshire Hospital which is in urgent need of accommodation. The new hospital will have 152 with administrative arrangements for an ultimate ca of 236 beds. At Lichfield the present Victoria C Hospital is to be replaced by a new building on anoth at a total cost of £23,500, towards which £13,500 is in There will be 34 beds instead of 21, and five private instead of two.

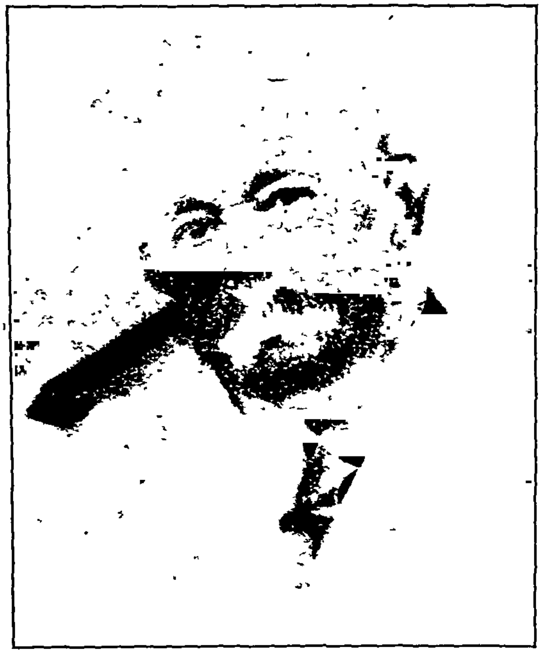
Hospital Costs.—Stockport Infirmary re a reduction of about 15*s.* per week in the av cost of an in-patient, in consequence of the fa the price of commodities; the amount last year £2 2*s.* 1½*d.* The daily average number of beds occ was 109, the average stay 17 days, and the av cost of each occupied bed £181 17*s.* 2*d.* At Tam Hospital there were 661 in-patients who stayed 22 on the average, and cost £2 17*s.* 2*d.* per week. Subj the approval of the Board of Education, Tyne education committee has decided to increase the max charge to parents for operations on their children for en tonsils and adenoids from £2 2*s.* to £1 4*s.*

OBITUARY

SIR FREDERICK ANDREWES, M.D. Oxf., F.R.C.P. Lond., F.R.S.,

RITUS PROFESSOR OF PATHOLOGY, UNIVERSITY OF LONDON.

HE death of Sir Frederick Andrewes, briefly iounced last week, took place on Feb. 24th after hort final illness, the sequel to the cerebral attack ered in New York in 1931, from which he had de so remarkable a recovery. In fact, though had been slowly losing ground, he had kept a at deal of his regained power and was able, even late as a month ago, to enjoy a walk and talk in ie of the sunnier intervals of a London winter. 'rof. Andrewes was in the seventy-third year of his and, as he told the Abernethian Society in the ghtful reminiscences imunicated at the e of his retirement n St. Bartholomew's, was born about the e at which bacterio- y was taking its first tative steps. It was, wever, many years ore he was drawn to study of that branch science. Always an er student of nature passed from school to ist Church, Oxford, as Junior Student, and owing his scientific bent k first-class honours in school of natural nce. A year later he awarded the Burdett-itts scholarship for the dy of geology and of ural science as bearing n geology. Already he l begun his medical eer by gaining an open olarship at the medical ool of St. Bartholo- w's; in 1886 he was ted to a medical fellow-p at Pembroke College, l in 1887 proceeded to medical degree of his University. In his student s he made his first essay in bacteriology by staining l proudly exhibiting the bacillus of Koch, at that le an entirely novel procedure in clinical medicine. was not however till 1890 that the influence of in, the real Father of Bacteriology in this country, ned his serious attention to this subject. It s in Klein's laboratory, in company with a small id of enthusiasts for the new science, that Andrewes an what were to be the determining studies for his ure career. In the next seven years, although continued his bacteriological work, it appeared ely that his life would be devoted to clinical dicine. He had served the usual junior appoint-nts at his hospital, had been casualty physician, d had been elected assistant physician to the al Free Hospital. In these posts he had estab-ied a reputation for sound clinical work and able ching; his ideas were then wholly of clinical ctice and of a place on the staff. Yet when in 97 his intimate friend and forerunner, Kanthack, first lecturer on pathology at St. Bart.'s, migrated to Cambridge to become professor of pathology, Andrewes seemed to be his obvious successor. He hesitated for a little, as was natural, but (to quote his own words) realised that he loved laboratory work more than out-patients—and accepted the task. So it was at the comparatively mature age of 38 that he entered upon the work which engrossed his activities for the next 32 years. How successful that work proved is common knowledge to all St. Bart.'s men, but his reputation grew quickly outside the walls of his own school, and he soon became recognised as one of the builders of the pathological and bacteriological science which now forms so essential a partof the foundations of medicine and surgery. Rapid and striking as the change has been in the period since he was thus appointed, he still looked forward to wider developments, and quite recently in conversation sketched the future of pathological science, ever enlarging its range till it should embrace the whole activities of medical work.



SIR FREDERICK ANDREWES.

[Photograph by J Russell.

The department at St. Bart.'s to which Andrewes was appointed in 1897 at first consisted only of himself and Dr. J H. Drysdale and occupied two rooms, but in a few years it grew to comprise many other workers and assistants. His share in this development was of course part of the general rise in the importance of pathology, yet in a particular sense he did more than any other pathologist to direct growth of the new science for the somewhat devious route which he had followed to attain to a leading position in pathology had given him a wider outlook on the relationship between pathology and medical science than was, or even now is, at all common. At his own school his interest in clinical and sanitary work was maintained by his appointments as physician to the nursing staff and sanitary officer to the hospital, and it was these intermissions from the laboratory bench, among other influences, which gave him the experience and vision which enabled him to link up the advancing science with the older departments of medicine. Bacteriology naturally claimed much of his attention, but for many years he spent time in the pathological museum of the hospi[illegible] adding to that collection and [illegible] his own knowledge till he had become an acknowledged authority, not only in naked-eye but in microscopic pathology. One of his earlier papers on the histology of Hodgkin's disease, at any rate in this country entirely original work, has stood the test of time. Meanwhile his reputation was spreading in wider circles, and he was one of the first men to be appointed to the committee which later became the Medical Research Council.

Wellcome and Co., Bovril, Ltd., Boots Pure Drug Co., and Parke, Davis and Co., to which firms the Council express grateful acknowledgments.

CERTAIN OTHER INVESTIGATIONS.

The effective concentration of *puerperal fever* cases at one centre (Queen Charlotte's Hospital) and the organised study of the disease by clinicians and laboratory workers in intimate association is in progress. NEW MIDLAND HOSPITALS.—The two cities Coventry and Lichfield, so long joined together one diocese, are simultaneously intending to erect r hospitals. Coventry is about to build an infecti hospital at a cost of £123,500, less £65,000 for wh the city council has sold the existing building to the Coven and Warwickshire Hospital which is in urgent need of m accommodation. The new hospital will have 152 b with administrative arrangements for an ultimate capa of 236 beds. At Lichfield the present Victoria Cott Hospital is to be replaced by a new building on another at a total cost of £23,500, towards which £13,500 is in ha There will be 34 beds instead of 21, and five private wa instead of two.

HOSPITAL COSTS.—Stockport Infirmary repo a reduction of about 15*s.* per week in the aver cost of an in-patient, in consequence of the fall the price of commodities; the amount last year £2 2*s.* 1½*d.* The daily average number of beds occu was 109, the average stay 17 days, and the aver cost of each occupied bed £184 17*s.* 2*d.* At Tamw Hospital there were 661 in-patients who stayed 22 d on the average, and cost £2 17*s.* 2*d.* per week. Subjec the approval of the Board of Education, Tynemo education committee has decided to increase the maxim charge to parents for operations on their children for enlar tonsils and adenoids from £2 2*s.* to £1 4*s.*

CORRESPONDENCE

TUBERCULOSIS OF CHILDHOOD.

To the Editor of THE LANCET.

—In view of the report recently issued by the
al Research Council (P. D'Arcy Hart: The
of Tuberculin Tests in Man) we feel that Dr.
Fletcher's paper in your last issue was some-
provocative in nature. While allowing for his
pt to meet expected criticism there are, surely,
who would challenge the manner in which he
lected his "normal" children. Many of the
gs at the Henry Phipps Institute (in spite of
xpenditure of time, money, and energy) have
een confirmed by workers in this country.
letcher is to be commended on his deviation
Opie and McPhedran's routine. Radiology
er is a good servant but a bad master, and we
at some at any rate of Dr. Fletcher's diagnoses,
almost solely on radiological findings, are
to serious criticism.

of Hart's main conclusions is that a child of
age, who fails to react to tuberculin, is not
ng with *tuberculosis*. whatever else may be
use of his signs or symptoms. The illustrations
of the cases. particularly in view of the remark-
short after-histories, may well be those of
pletely resolved pneumonic conditions. Such
are far from rare in tuberculosis dispensaries
dequate X ray facilities. Nor does Dr. Fletcher
on what he bases his diagnosis of "tuberculous
eo-bronchial glands" in four children, in only
f whom was a positive tuberculin test recorded.
s again was founded only on radiological evidence
y be forgiven for quoting the conclusions reached
e committee appointed by the National Tubercu-
Association of America to study the "Clinical
X ray findings in the chests of normal children":

> *he normal chest.*—The normal chest of the child from
> oentgenological standpoint is subject to such wide
> ions within normal limits as to be beyond the possibility
> ct description.
>
> *ilum shadow.*—The conglomerate shadow, commonly
> the hilum shadow, when found lying entirely within
> ner third or zone of the lung area can be disregarded
> arded as normal). except where it is made up of a solid
> of homogeneous shadow giving undoubted evidence
> t represents a growth or mediastinal pleurisy.
>
> *lcified nodes.*—Calcified nodes at the root of the lung,
> ut evidence of lung disease. are of no significance except
> ossible evidence of some healed inflammatory condition, possibly but not necessarily tuberculous. They are a common finding in normal chests."

Wessler and Jaches, in remarking on enlarged root shadows, also state that "to regard these shadows as evidence of involvement of the lung root in a tuberculous infiltration is fatal to a rational interpretation of the plates; a large percentage of mankind would then be pronounced clinically tuberculous and the Rontgen diagnosis would be reduced to an absurdity."

Dr. Fletcher reaches the conclusion that tuberculosis of childhood is liable to develop without close contact with a known case. He does not state whether he has taken the necessary step of securing the examination of the parents of these children. In a preliminary series investigated in the Bermondsey Tuberculosis Dispensary. in those families where it was possible to secure a thorough examination of both parents, we found that of 16 infants who had died of miliary or meningeal tuberculosis 15 had been in close contact with definite cases of pulmonary tuberculosis. In eight of these cases the father was suffering with pulmonary tuberculosis, and in four cases the mother. and in the remaining three instances a known (sputum positive) case was living in the same house. Further, in a series of ten consecutive cases of pulmonary tuberculosis (sputum positive) in children of school age, eight of them had been in recent contact with definite cases of the disease. To quote Dr. Fletcher, "it seems that there is still a large amount of accidental tuberculosis abroad," but in England. to judge from our experience, infection in childhood is not quite so accidental!

We have no desire to enlarge on the disadvantage of labelling a child as tuberculous without justification, but this question is of more than academic interest. The mere notification of a case of tuberculosis (and this is compulsory) sets in motion administrative action which, though it might vary from one area to another, involves the expenditure of money by the State. Clerks are employed to keep registers. Returns, often in duplicate, must be made to higher authorities; nurses are employed to visit the homes; tuberculosis officers are employed to supervise this work, to examine the contacts, and to effect prompt treatment when necessary. One unjustifiable notification, therefore, leads to expense by the State, even if nothing further is done. If, however, institutional treatment follows, as it often does quite automatically, the expense mounts at once.

At a time when the country is faced with a severe economic crisis surely these factors should be considered very closely. Dr. Burrell has repeatedly stressed the inadvisability of expending on the treatment of debilitated children large sums of money which have really been earmarked for dealing with true cases of tuberculosis and which would probably lead to greater efficiency if applied solely for this purpose. A glance at the reports of the Lancashire tuberculosis scheme will reveal that adequate provision can be made for all tuberculous children at relatively small cost, leaving the administration a freer hand to deal with the major problems confronting it.

We are, Sir, yours faithfully,

C. H. C. TOUSSAINT,
E. J. MACINTYRE.

(*Continued from previous page.*)

ng experience at the B.T.H. works. Rugby,
Dye was appointed a member of the staff of the
rical standards division of the National Physical
ratory, becoming head of this department on
transference of his chief Mr. F. E. Smith (now
Frank Smith) to the Admiralty. Dr. Dye was
ly interested in the methods for evaluating and
dardising the primary electrical units and did
h highly accurate work upon inductance and
city. He also contributed to the development
odern methods of measurement of time and this
ght him into contact with the Radio Research
rd and for several years he acted as chairman of
Commission on Radio Standards. Dr. Dye was
ed a Fellow of the Royal Society in 1928, and his
y death will be felt in more than one branch of
ntific work.

It was on this committee and on its various subcommittees that he did what was perhaps his most valuable work, especially during the period of the war. The part he played in the organisation and mobilisation of the forces required to deal with the new medical problems which crowded in during those four years is probably known to few; there were in fact not many of the urgent pathological investigations to which his knowledge, his wide experience of men and methods, and his balanced judgment of results did not materially contribute. This work was recognised in 1920 by the award of a knighthood. Other honours came to him. He was elected a Fellow of the Royal Society, an Honorary D.C.L. of Durham University, Croonian lecturer of the Royal College of Physicians of London in 1910, and Harveian orator in 1920.

Perhaps the work which was his most favoured field was the study of the streptococci. Alone and with others he wrote much on this subject, and though later work, some of it his own, has invalidated many of the actual results, the labour devoted to these studies served to erect much of the essential scaffolding of bacteriological theory. Of recent years he had returned to these aspects of bacteriology and had specially studied the antigenic structure of bacteria as demonstrated by their agglutinative reactions, amassing knowledge regarding the variation of bacterial strains. This work he had continued after retirement from his professorship, and at the time of his death he was occupied with the revision and collation of his research work. Apart from his main contributions to pathology he had on various occasions charmed the more intimate circle of his friends by "parerga" which none but he could have written. One of these entitled "The Romance of the Streptococci" was a skit on his own lectures; another his own account of recovery, at first slow then rapid, of his power of speech after the cerebral attack. Both of these have the vivid presentation, the perfected phrase, the humorous innuendo, and the balanced style which always marked his papers.

Andrewes was not, as measured by the standard of the past, a great pathologist; he would himself have claimed only to have cultivated his small patch of garden to the best of his ability, with the same care and eager pleasure with which he occupied his leisure in his rock-garden. But he was certainly in this country one of the leaders in the development of bacteriological and pathological science; a builder with power to select and reject material and results so as to form firm foundations. His influence has been and will be more widely felt in the example he gave of tireless industry, scrupulous accuracy, skilful exposition, critical judgments, and a power of inspiring all who came in contact with him.

Sir Frederick Andrewes married in 1895 Phyllis Mary, daughter of John Hamer, J.P. Their only son is on the scientific staff of the National Institute of Medical Research.

CHARLES WALKER CATHCART, C.B.E., M.B. Edin., F.R.C.S. Eng.

By the death of Mr. C. W. Cathcart the Edinburgh school loses a distinguished veteran teacher. It is true that Cathcart belongs rather to the last generation than to this; but in his eightieth year he was still a living presence in both the medical and the social life of Edinburgh.

Graduating as M.A. in 1873, and as M.B., C.M. in 1878, he attained the surgical Fellowships of England in 1879 and of Edinburgh in 1880, having previously served as house surgeon to Annandale at the Royal Infirmary. In due course he joined the staff of thi hospital as assistant surgeon, and, tying for the Liston Victoria jubilee prize of the Royal College of Surgeons of Edinburgh in 1893, became full surgeon in 1899. He was an authority on surgical pathology, and for a long time was conservator of the College of Surgeons museum. He conducted classes on systematic and operative surgery in the Edinburgh School of Medicine and later was a lecturer in the Royal Infirmary. A the outbreak of war, in 1914, he held the rank o lieut.-colonel in the Territorials, and he had a grea deal to do with the equipping of the Second Scottis General Hospital at Craigleith. Afterwards he wa surgeon to the general military hospital at Bangou and at the end of the war he was appointed to th staff of the Edenhall Hostel for Limbless Soldie and Sailors. For his war services he was create C.B.E.

These are the externals of Cathcart's career as surgeon. But such a record gives little idea of h personality. "He was a man of great originality writes a colleague; "one could not talk with hi for five minutes without hearing some fresh ide In the laboratory he was as facile as in the surgic ward. Cathcart's microtome was familiar to medic students more than 40 years ago. He was continual devising something new. He was a born teach which means that he was always a student a understood the student mind from within. T 'Surgical Handbook' of Caird and Cathcart w the constant companion of the house surgeon. Bo men had ingenious minds, and their combination authors would be hard to better. As late as 19 Cathcart, in collaboration with Mr. Hartley, p duced a text-book with the title 'Requisites a Methods in Surgery.' Early in the war he was believe, the first to suggest sphagnum moss as convenient surgical dressing, and started the orga sation for collecting it. In social affairs he was c tinually working to improve the life of the poor- diet and otherwise. But these high-tension activi had to be paid for and, although an athletic man his early days, he was forced in middle life to t a year's sea voyage. It was not quite successful clearing off his insomnia, and he found the voya which included Australia, less a rest than a discipl But Cathcart, on resuming work at home, beca once more the same fertile, quiet influence in medical school, and it was a stimulus to hear him the Medico-Chirurgical Society. In the war his o son was killed, and the death was a great blow a man of highly emotional nature; but as a memo to the son he devised a play centre in one of poorer quarters. He was, in fact, a practical soci gist as well as a surgeon.

"In the story of the Medical School of Edinbu Cathcart will be found as a man in the great suc sion of Edinburgh surgeons; modest and un tentious, yet creating an atmosphere of conscienti devotion to duty and establishing a record of techn work on the highest practical plane."

WILLIAM DAVID DYE, D.Sc., F.R.S.

We regret to record the death of Mr. William Dye, D.Sc., A.C.G.I., at the early age of 44. Dr. I was the third son of Mr. Charles Dye, J.P., Portsmouth. After taking the D.Sc. Lond.,

CORRESPONDENCE

TUBERCULOSIS OF CHILDHOOD.

To the Editor of THE LANCET.

R,—In view of the report recently issued by the cal Research Council (P. D'Arcy Hart: The e of Tuberculin Tests in Man) we feel that Dr. st Fletcher's paper in your last issue was some- provocative in nature. While allowing for his npt *to meet expected criticism there are*, surely, y who would challenge the manner in which he selected his "normal" children. Many of the ngs at the Henry Phipps Institute (in spite of expenditure of time, money, and energy) have been confirmed by workers in this country. Fletcher is to be commended on his deviation 1 Opie and McPhedran's routine. Radiology ever is a good servant but a bad master, and we that some at any rate of Dr. Fletcher's diagnoses, d almost solely on radiological findings, are i to serious criticism.

ne of Hart's main conclusions is that a child of ol age, who fails to react to tuberculin, is not ering with tuberculosis, whatever else may be cause of his signs or symptoms. The illustrations wo of the cases, particularly in view of the remark- short after-histories, may well be those of mpletely resolved pneumonic conditions. Such s are far from rare in tuberculosis dispensaries h adequate X ray facilities. Nor does Dr. Fletcher te on what he bases his diagnosis of "tuberculous cheo-bronchial glands" in four children, in only of whom was a positive tuberculin test recorded. his again was founded only on radiological evidence may be forgiven for quoting the conclusions reached the committee appointed by the National Tubercu- is Association of America to study the "Clinical d X ray findings in the chests of normal children":

> "*The normal chest.*—The normal chest of the child from roentgenological standpoint is subject to such wide iations within normal limits as to be beyond the possibility exact description.
>
> "*Hilum shadow.*—The conglomerate shadow, commonly lled the hilum shadow, when found lying entirely within inner third or zone of the lung area can be disregarded regarded as normal), except where it is made up of a solid ss of homogeneous shadow giving undoubted evidence at it represents a growth or mediastinal pleurisy.
>
> "*Calcified nodes.*—Calcified nodes at the root of the lung, thout evidence of lung disease, are of no significance except a possible evidence of some healed inflammatory condition, possibly but not necessarily tuberculous. They are a common finding in normal chests."

Wessler and Jaches, in remarking on enlarged root shadows, also state that "to regard these shadows as evidence of involvement of the lung root in a tuberculous infiltration is fatal to a rational interpretation of the plates; a large percentage of mankind would then be pronounced clinically tuberculous and the Rontgen diagnosis would be reduced to an absurdity."

Dr. Fletcher reaches the conclusion that tuberculosis of childhood is liable to develop without close contact with a known case. He does not state whether he has taken the necessary step of securing the examination of the parents of these children. In a preliminary series investigated in the Bermondsey Tuberculosis Dispensary, in those families where it was possible to secure a thorough examination of both parents, we found that of 16 infants who had died of miliary or meningeal tuberculosis 15 had been in close contact with definite cases of pulmonary tuberculosis. In eight of these cases the father was suffering with pulmonary tuberculosis, and in four cases the mother, and in the remaining three instances a known (sputum positive) case was living in the same house. Further, in a series of *ten* consecutive cases of pulmonary tuberculosis (sputum positive) in children of school age, eight of them had been in recent contact with definite cases of the disease. To quote Dr. Fletcher, "it seems that there is still a large amount of accidental tuberculosis abroad," but in England, to judge from our experience, infection in childhood is not quite so accidental!

We have no desire to enlarge on the disadvantage of labelling a child as tuberculous without justification, but this question is of more than academic interest. The mere notification of a case of tuberculosis (and this is compulsory) sets in motion administrative action which, though it might vary from one area to another, involves the expenditure of money by the State. Clerks are employed to keep registers. Returns, often in duplicate, must be made to higher authorities; nurses are employed to visit the homes; tuberculosis officers are employed to supervise this work, to examine the contacts, and to effect prompt treatment when necessary. One unjustifiable notification, therefore, leads to expense by the State, even if nothing further is done. If, however, institutional treatment follows, as it often does quite automatically, the expense mounts at once.

At a time when the country is faced with a severe economic crisis surely these factors should be considered very closely. Dr. Burrell has repeatedly stressed the inadvisability of expending on the treatment of debilitated children large sums of money which have really been earmarked for dealing with true cases of tuberculosis and which would probably lead to greater efficiency if applied solely for this purpose. A glance at the reports of the Lancashire tuberculosis scheme will reveal that adequate provision can be made for all tuberculous children at relatively small cost, leaving the administration a freer hand to deal with the major problems confronting it.

BLOOD GROUPING OF MONGOLIAN IMBECILES.

To the Editor of THE LANCET.

R.—I am grateful to Mr. Geoffrey Keynes for ing a point which perhaps was not made clear my paper of Feb. 20th. It was certainly not my ntion to assume the existence of a linkage between ngol characters and either agglutinogen. My argument, such as it was, relied entirely on the fact that A and B are inherited as dominant characters, so that, for example, a high incidence of one of these characters among ancestors tends to produce a high incidence of this same character among the descendants. The distribution of the blood groups in the "Mongolian imbeciles," therefore, shows that among their ancestors persons belonging to populations relatively rich in B (e.g., Eastern races) have not been more frequent than among the ancestors of the individuals in the control group.

Such a conclusion, I stated, seemed inconsistent with Dr. Crookshank's views. However, in his letter, Dr. Crookshank says that my observations do not conflict with his views, and of this he is the best judge. I am sorry to have misrepresented him.

I am, Sir, yours faithfully,

L. S. PENROSE.

Colchester, Feb. 29th, 1932.

CORRECTION.—In our issue of Nov. 28th, writing from Semaphore, Australia, in reference to Darwin's naval service, Dr. F. Lucas Benham gave the name of the Captain of H.M.S. *Rattlesnake* as Owen Smyth. He should have written Owen Stanley, he informs us, a name whose familiarity is due to the fact that it has been bestowed on the highest mountain in British New Guinea.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

DANGEROUS DRUGS—IMPORT DUTIES.

N Feb. 25th the Dangerous Drugs Bill was agreed on Report.

The Committee stage being completed, the Import ties Bill was reported to the House on Feb. 23rd, er which amendments were accepted (1) providing at scientific films should continue to enjoy the vilege conferred on them by the Act of 1928, and putting cinchona bark, cork, cork shavings, d waste cork on the free list. On Feb. 25th the ll was read the third time by 442 votes to 62—jority 380.

In the House of Lords on Feb. 29th the Import ties Bill passed through all its stages and was given e Royal Assent.

VIVISECTION AND CHEMICAL WARFARE.

On March 1st, in the House of Commons, Mr. ROVES presented a petition against the legal practice vivisection and the use of poison gas in warfare. The tition was signed by over 160,000 citizens.

SCIENTIFIC SLAUGHTER OF ANIMALS.

On March 1st, in the House of Commons, Lieut.-lonel MOORE asked leave to present a Bill to ovide for the humane and scientific slaughter of imals. He said that he introduced a similar Bill st year, but after it had passed half-way through e committee stage the national crisis supervened. he Bill sought to ensure that all animals killed for man food should be slaughtered by a mechanical strument, instead of by the present pole-axe method. f 1500 local authorities, 500 had voluntarily adopted he by-law of the Ministry of Health to this end, and many practising butchers had followed their example. he Bill was promoted by the Royal Society for the revention of Cruelty to Animals. He had decided, o avoid criticism, to withdraw pigs from the scope f the Bill. Sixteen million animals were involved early, and because of the voluntary action of certain local authorities 4,000,000 of them had been relieved of suffering.

Leave was given to introduce the Bill, and it was brought in and read a first time.

HOUSE OF COMMONS.

WEDNESDAY, FEB. 24TH.

Establishment of Naval Surgeons.

Mr. RALPH BEAUMONT asked the First Lord of the Admiralty whether the establishment of naval surgeons was complete; and, if not, what was the deficiency.—Lord STANLEY (Parliamentary Secretary to the Admiralty) replied: The establishment of naval medical officers is not complete, the deficiency at present being approximately 60.

Mr. BEAUMONT: Is it proposed to take any steps to make up that deficiency?

Lord STANLEY: Yes, the whole question of the conditions of service, recruitment, &c., in the medical branches of the three Services is under consideration by an inter-departmental committee.

Prison Administration.

Mr. GORDON MACDONALD asked the Home Secretary what action he intended to take with regard to the request made to him for the setting up of a Royal Commission to investigate and report upon the whole question of prison administration with special reference to prison industries.—Sir HERBERT SAMUEL replied: I am of opinion that the system of prison industries needs review. As I stated recently in answer to a question, a committee was appointed by my predecessor to consider the best methods of dealing with persistent offenders, and I understand that the report of that committee, which is expected to be completed in a few weeks from now, will call attention to the need for the improvement of prison industries in connexion with other proposals. When this report is received, I will consider what would be the right procedure to adopt, but, as at present advised, I do not think that the appointment of a Royal Commission would be the best means of investigating the somewhat detailed and technical questions that are involved, or would conduce to the speedy action which may prove to be desirable.

Encephalitis and Vaccination.

Mr. GROVES asked the Minister of Health how many cases of encephalitis following vaccination had been reported either direct to the Ministry of Health or through the Andrewes and Rolleston vaccination committees, from the first sitting of the Andrewes committee down to the present time; how many of these had been included in the cases admitted to be cases of injury to the nervous system resulting from vaccination; and how many fatal cases were similarly reported.—Sir E. HILTON YOUNG replied: During the period under consideration by the Andrewes Committee and the Rolleston Committee—i.e., since November, 1922—202 cases of encephalitis following vaccination have come to the notice of my department. Of these cases, 197 were;

ARTIFICIAL PNEUMOTHORAX.

To the Editor of THE LANCET.

SIR,—The note in your issue of Feb. 27th (p. 450) by Dr. J. D. Macfie and Dr. A. J. P. Alexander on the follow-up of artificial pneumothorax cases is of great interest and importance. With their assessment of the practical value of this method of treatment I am entirely in agreement, but it would be of special interest to know further details of the cases that have died, particularly as regards the mode of death. It is to be hoped that they will publish a more extended study at a later date.

It is, I think, to be regretted that more investigation has not been carried out in this country on a really large scale as to the ultimate cause of death in cases of pulmonary tuberculosis treated by artificial pneumothorax, with special reference to the spread of disease in the contralateral lung. Even now, despite all the work that has been done by different observers and the vast amount of material available for statistical purposes, we are still to a large extent ignorant of the factors which should go to form the criterion of suitability in our selection of cases for pneumothorax treatment. My impression, after some years of clinical experience, is that phthisical patients fall roughly into three groups: those that go downhill whatever treatment is employed, those that recover and achieve permanent arrest in almost any circumstances, and those that occupy a middle position, so to speak, in whom one's treatment may well be the deciding force between life and death. I am inclined to think that it is the last group which furnishes the most successful results in pneumothorax treatment. Moreover, there is, I believe, a strong impression among many who have worked at the subject that while the immediate prognosis of pulmonary tuberculosis is more favourable in A.P. cases, the ultimate outlook—i.e., as regards length of life—is better in patients in whom cure has been attempted by more natural means.

I am, Sir, yours faithfully,
MAURICE DAVIDSON.

Wimpole-street, W., Feb. 28th, 1932.

A CAMP FOR UNEMPLOYED MEN.

To the Editor of THE LANCET.

SIR,—We believe that it is within the experience of all medical men in general practice that chronic unemployment almost inevitably leads to deterioration of mental and physical health, and that this adds to the difficulty of re-entering organised industry. With unemployment as widespread as it is now, the progressive inefficiency in the community from this cause becomes a menace not only to the happiness of millions, but to our communal ability to take the initiative if opportunities present themselves for a revival of trade, and to our capacity for reorganising our social structure if progressive rationalisation of industry demands it.

We are closely associated with a group of social workers known as the Order of Woodcraft Chivalry, which has set on foot a scheme of national non-military service. This has been devised so as to give opportunity to all young men who have either voluntary or involuntary leisure, to devote it to a full-time camp course of training, directed to the maintenance of physical fitness, mental alertness, initiative, and citizenship.

We are not yet ready to undertake the regeneration of demoralised men, though we hope to be so soon. Our first pioneer group, which will go into camp in March, must grow at first by the addition of men of courage, initiative, and vision, capable of building up a tradition of hardihood and mutual help; and the purpose of this letter is to ask that the names and addresses of such men—great numbers of whom must be known to your readers—may be sent to the hon. secretary at 2, Devonshire-place, W.1. They should be between the ages of 18 and 25. If they ar entitled to unemployment or transitional benefits the Ministry of Labour has agreed that these may b paid over for their maintenace while under training.

We shall be very glad to supply full information t anyone interested.

We are, Sir, yours faithfully,
(Sgd.) I. NORMAN GLAISTER, D. L. TUCKER,
E. SCHOFIELD, R. TURNER,
B. STANLEY, A. WESTLAKE.
F. TALBOT,

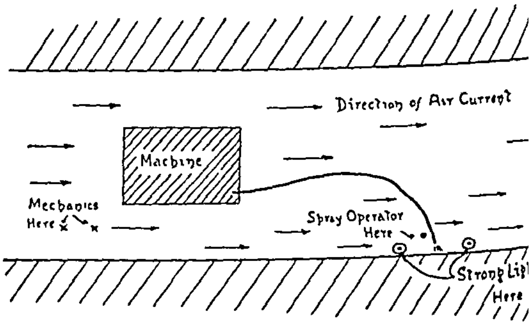
2, Devonshire-place, W., Feb. 27th, 1932.

ASBESTOS IN LONDON TUBE RAILWAYS.

To the Editor of THE LANCET.

SIR,—With reference to the annotation on page 41 of your issue of Feb. 20th, we, as inventors of th process referred to, give you herewith a few particulars, which we trust will enable you to arrive at better conception of the work which is at preser being carried out in the London Underground tunnel Particular attention is drawn by you to the Hom Office inquiry into the effects of asbestos dust on th lungs, and it will be seen that ventilation and th replacement, wherever possible, of dry processes wet, form the basis of the safeguards recommende of which advantage has been taken by the designe of our apparatus.

As will be seen on examination of "Methods for St pressing Dust in Asbestos Textile Factories," issued the Home Office (1931), a system of tunnels sho on pages 11, 31, and plate opposite page 36, wh are reproductions of photographs taken in our fact provides an incoming supply of fresh air, remov any possible traces of dust from the vicinity of worker, and we would point out that this is exa what takes place in the Underground tunnel, apparatus being so arranged that the operato kept constantly supplied with fresh air, and dust or atomised adhesive is blown away from immediately by the natural current of air flov through the tunnel, assisted where necessary mechanical means, for which full provision has made.



In addition, a special study has been made of question of suitable adhesives, so that suffic liquid can be used through the second projecto completely saturate the fibre delivered from the o

e. This in itself removes the possibility of dry les of fibre escaping into the surrounding sphere. We would add that, contrary to your ption, a minimum air pressure is maintained e fibre nozzle, and perhaps the rough sketch hed will enable you to see how full advantage een taken of the natural conditions prevailing e tunnel system.

fore this work was commenced, a very thorough igation of our process was made by the engineers e London Underground railways, and we can e you that no pains are being spared to make thoroughly satisfactory in every respect.

We are, Sir, yours faithfully,

J. W. ROBERTS, LTD.,
ey, Leeds, Feb. 29th, 1932. Asbestos Manufacturers.

BLOOD GROUPING OF MONGOLIAN IMBECILES.

To the Editor of THE LANCET.

R.—I am grateful to Mr. Geoffrey Keynes for ng a point which perhaps was not made clear y paper of Feb. 20th. It was certainly not my tion to assume the existence of a linkage between gol characters and either agglutinogen. My argument, such as it was, relied entirely on the fact that A and B are inherited as dominant characters, so that, for example, a high incidence of one of these characters among ancestors tends to produce a high incidence of this same character among the descendants. The distribution of the blood groups in the "Mongolian imbeciles," therefore, shows that among their ancestors persons belonging to populations relatively rich in B (e.g., Eastern races) have not been more frequent than among the ancestors of the individuals in the control group.

Such a conclusion, I stated, seemed inconsistent with Dr. Crookshank's views. However, in his letter, Dr. Crookshank says that my observations do not conflict with his views, and of this he is the best judge. I am sorry to have misrepresented him.

I am, Sir, yours faithfully,

Colchester, Feb. 29th, 1932. L. S. PENROSE.

CORRECTION.—In our issue of Nov. 28th, writing from Semaphore, Australia, in reference to Darwin's naval service, Dr. F. Lucas Benham gave the name of the Captain of H.M.S. *Rattlesnake* as Owen Smyth. He should have written Owen Stanley, he informs us, a name whose familiarity is due to the fact that it has been bestowed on the highest mountain in British New Guinea.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

DANGEROUS DRUGS—IMPORT DUTIES.

N Feb. 25th the Dangerous Drugs Bill was agreed n Report.

he Committee stage being completed, the Import ies Bill was reported to the House on Feb. 23rd, n which amendments were accepted (1) providing t scientific films should continue to enjoy the vilege conferred on them by the Act of 1928, and putting cinchona bark, cork, cork shavings, d waste cork on the free list. On Feb. 25th the l was read the third time by 442 votes to 62—jority 380.

In the House of Lords on Feb. 29th the Import ties Bill passed through all its stages and was given e Royal Assent.

VIVISECTION AND CHEMICAL WARFARE.

On March 1st, in the House of Commons, Mr. oves presented a petition against the legal practice vivisection and the use of poison gas in warfare. The tition was signed by over 160,000 citizens.

SCIENTIFIC SLAUGHTER OF ANIMALS.

On March 1st, in the House of Commons, Lieut.-lonel MOORE asked leave to present a Bill to ovide for the humane and scientific slaughter of imals. He said that he introduced a similar Bill st year, but after it had passed half-way through e committee stage the national crisis supervened. he Bill sought to ensure that all animals killed for man food should be slaughtered by a mechanical strument, instead of by the present pole-axe method. f 1500 local authorities, 500 had voluntarily adopted e by-law of the Ministry of Health to this end, and any practising butchers had followed their example. he Bill was promoted by the Royal Society for the revention of Cruelty to Animals. He had decided, o avoid criticism, to withdraw pigs from the scope f the Bill. Sixteen million animals were involved early, and because of the voluntary action of certain cal authorities 4,000,000 of them had been relieved of suffering.

Leave was given to introduce the Bill, and it was brought in and read a first time.

HOUSE OF COMMONS.

WEDNESDAY, FEB. 24TH.

Establishment of Naval Surgeons.

Mr. RALPH BEAUMONT asked the First Lord of the Admiralty whether the establishment of naval surgeons was complete; and, if not, what was the deficiency.—Lord STANLEY (Parliamentary Secretary to the Admiralty) replied: The establishment of naval medical officers is not complete, the deficiency at present being approximately 60.

Mr. BEAUMONT: Is it proposed to take any steps to make up that deficiency?

Lord STANLEY: Yes, the whole question of the conditions of service, recruitment, &c., in the medical branches of the three Services is under consideration by an interdepartmental committee.

Prison Administration.

Mr. GORDON MACDONALD asked the Home Secretary what action he intended to take with regard to the request made to him for the setting up of a Royal Commission to investigate and report upon the whole question of prison administration with special reference to prison industries.—Sir HERBERT SAMUEL replied: I am of opinion that the system of prison industries needs review. As I stated recently in answer to a question, a committee was appointed by my predecessor to consider the best methods of dealing with persistent offenders, and I understand that the report of that committee, which is expected to be completed in a few weeks from now, will call attention to the need for the improvement of prison industries in connexion with other proposals. When this report is received, I will consider what would be the right procedure to adopt, but, as at present advised, I do not think that the appointment of a Royal Commission would be the best means of investigating the somewhat detailed and technical questions that are involved, or would conduce to the speedy action which may prove to be desirable.

Encephalitis and Vaccination.

Mr. GROVES asked the Minister of Health how many cases of encephalitis following vaccination had been reported either direct to the Ministry of Health or through the Andrewes and Rolleston vaccination committees, from the first sitting of the Andrewes committee down to the present time; how many of these had been included in the cases admitted to be cases of injury to the nervous system resulting from vaccination; and how many fatal cases were similarly reported.—Sir E. HILTON YOUNG replied: During the period under consideration by the Andrewes Committee and the Rolleston Committee—i.e., since November, 1922—202 cases of encephalitis following vaccination have come to the notice of my department. Of these cases, 197 were;

ARTIFICIAL PNEUMOTHORAX.

To the Editor of THE LANCET.

SIR,—The note in your issue of Feb. 27th (p. 450) by Dr. J. D. Macfie and Dr. A. J. P. Alexander on the follow-up of artificial pneumothorax cases is of great interest and importance. With their assessment of the practical value of this method of treatment I am entirely in agreement, but it would be of special interest to know further details of the cases that have died, particularly as regards the mode of death. It is to be hoped that they will publish a more extended study at a later date.

It is, I think, to be regretted that more investigation has not been carried out in this country on a really large scale as to the ultimate cause of death in cases of pulmonary tuberculosis treated by artificial pneumothorax, with special reference to the spread of disease in the contralateral lung. Even now, despite all the work that has been done by different observers and the vast amount of material available for statistical purposes, we are still to a large extent *ignorant of the factors which should go to form the* criterion of suitability in our selection of cases for pneumothorax treatment. My impression, after some years of clinical experience, is that phthisical patients fall roughly into three groups: those that go downhill whatever treatment is employed, those that recover and achieve permanent arrest in almost any circumstances, and those that occupy a middle position, so to speak, in whom one's treatment may well be the deciding force between life and death. I am inclined to think that it is the last group which furnishes the most successful results in pneumothorax treatment. Moreover, there is, I believe, a strong impression among many who have worked at the subject that while the immediate prognosis of pulmonary tuberculosis is more favourable in A.P. cases, the ultimate outlook—i.e., as regards length of life—is better in patients in whom cure has been attempted by more natural means.

I am, Sir, yours faithfully,
MAURICE DAVIDSON.

Wimpole-street, W., Feb. 28th, 1932.

A CAMP FOR UNEMPLOYED MEN.

To the Editor of THE LANCET.

SIR,—We believe that it is within the experience of all medical men in general practice that chronic unemployment almost inevitably leads to deterioration of mental and physical health, and that this adds to the difficulty of re-entering organised industry. With unemployment as widespread as it is now, the progressive inefficiency in the community from this cause becomes a menace not only to the happiness of millions, but to our communal ability to take the initiative if opportunities present themselves for a revival of trade, and to our capacity for reorganising our social structure if progressive rationalisation of industry demands it.

We are closely associated with a group of social workers known as the Order of Woodcraft Chivalry, which has set on foot a scheme of national non-military service. This has been devised so as to give opportunity to all young men who have either voluntary or involuntary leisure, to devote it to a full-time camp course of training, directed to the maintenance of physical fitness, mental alertness, initiative, and citizenship.

We are not yet ready to undertake the regeneration of demoralised men, though we hope to be so soon. Our first pioneer group, which will go into camp March, must grow at first by the addition of men courage, initiative, and vision, capable of building up a tradition of hardihood and mutual help; and the purpose of this letter is to ask that the names and addresses of such men—great numbers of whom must be known to your readers—may be sent to the hon. secretary at 2, Devonshire-place, W.1. They should be between the ages of 18 and 25. If they ar entitled to unemployment or transitional benefits the Ministry of Labour has agreed that these may b paid over for their maintenace while under training.

We shall be very glad to supply full information t anyone interested.

We are, Sir, yours faithfully,
(Sgd.) I. NORMAN GLAISTER, D. L. TUCKER,
E. SCHOFIELD, R. TURNER,
B. STANLEY, A. WESTLAKE.
F. TALBOT,

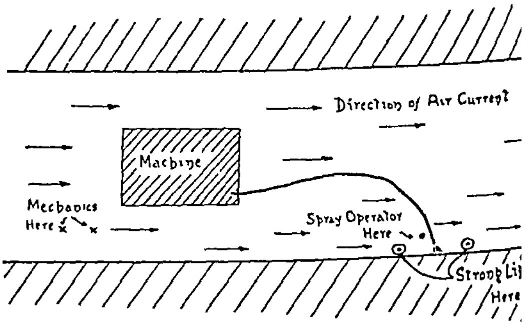
2, Devonshire-place, W., Feb. 27th, 1932.

ASBESTOS IN LONDON TUBE RAILWAYS.

To the Editor of THE LANCET.

SIR,—With reference to the annotation on page 4 of your issue of Feb. 20th, we, as inventors of t process referred to, give you herewith a few part culars, which we trust will enable you to arrive at better conception of the work which is at prese being carried out in the London Underground tunne Particular attention is drawn by you to the Ho Office inquiry into the effects of asbestos dust on t lungs, and it will be seen that ventilation and t replacement, wherever possible, of dry processes wet, form the basis of the safeguards recommend of which advantage has been taken by the design of our apparatus.

As will be seen on examination of "Methods for S pressing Dust in Asbestos Textile Factories," issue the Home Office (1931), a system of tunnels sh on pages 11, 31, and plate opposite page 36, w are reproductions of photographs taken in our fact provides an incoming supply of fresh air, remo any possible traces of dust from the vicinity of worker, and we would point out that this is exa what takes place in the Underground tunnel, apparatus being so arranged that the operat kept constantly supplied with fresh air, and dust or atomised adhesive is blown away from immediately by the natural current of air flo through the tunnel, assisted where necessary mechanical means, for which full provision has made.



In addition, a special study has been made of question of suitable adhesives, so that suffi liquid can be used through the second projecto completely saturate the fibre delivered from the c

ent examinations the following candidates were sful:—

ry.—A. Kobylsker and W. W. Perry, Guy's Hosp.
ery.—R. R. Chapman, St. Mary's Hosp.; B. Duval, of Durham; W. Hertzog, Guy's Hosp.; J. L. F. King, ng Cross Hosp.; M. S. Myles, Royal Free Hosp.; C. F. ing Cross Hosp.; G. W. Sturgess, St. Bart.'s ; F. A. Trembleday and C. F. Verey, St. Mary's Hosp.; G. Yencoll, Guy's Hosp.
nce Medicine.—G. A. Duncan and W. S. Pitt Payne, Hosp., and L. R. C. Rose, Univ. of Manchester.
ifery.—G. W. Aston, Univ. of Birmingham; L. A. Univ. of Sheffield; and W. Hertzog and A. Kobylsker, Guy's Hosp.

following candidates, having completed the final examination, have been granted the Diploma of the Society entitling to practise medicine, surgery, and midwifery: R. R. W. W. Perry, W. Hertzog, G. W. Sturgess, J. L. F. and C. F. Verey.

al Society of Arts.

r. J. C. Drummond, D.Sc., professor of biochemistry, the University of London, will give three lectures on nt Researches on the Nature and Function of Vitamins. the house of the Royal Society of Arts, John-street, London, W.C., on Mondays, April 18th and 25th, May 2nd at 8 P.M.

gress on Biliary Lithiasis.

n International Congress on Biliary Lithiasis will be d at Vichy from Sept. 19th to 22nd. The principal s of discussion will be the Sequelæ of Cholecystectomy, dical and Hydro-mineral Treatment of Cholecystitis ary Lithiasis, and the Cholelithiatic Liver. Inquiries ld be addressed to the secretary-general of the Congress, Boulevard des Capucines, Paris.

ntal Deficiency and Allied Conditions.

course of lectures for medical practitioners on Mental ciency and other Mental Conditions Closely Allied to it, be held at the University of London, Imperial Institute d, South Kensington, London, S.W., from April 11th d supplemented by a course of clinical instruction. e lecturers will include Dr. A. F. Tredgold, Dr. F. C. hell, Prof. Cyril Burt, Dr. W. Rees Thomas, Dr. am Moodie, and Dr. Emanuel Miller. Further ticulars may be had from Miss Evelyn Fox, c/o University ension Dept., at the above address.

fred Fripp Memorial Fellowship.

On Feb. 26th, at University College, Mr. Stanley Baldwin ed the first of the 20 annual lectures on Happiness d Success, for which Sir Alfred Fripp left a legacy. After ture Lord Goschen, the chairman, handed over to the s of Guy's Hospital the trust deeds of the Alfred p Fellowship, which has been founded to promote ch in the psychology of children. Election to the wship will be by a board of electors consisting of the ician for diseases of children, the superintendent and dean of the medical school of Guy's Hospital as ex-officio ers, and of five Members coöpted by them. The p Fellow will be allowed opportunities of study in the ren's department of the hospital, and candidates must ualified men or women, unmarried, and not more than years of age. The stipend will be £300 per annum, and Fellowship is to be regarded as a whole-time appointment, though it may be held concurrently with a onstratorship. It will be held ordinarily for two years.

Bacteriological Investigation of Puerperal Sepsis.

By arrangement between the Ministry of Health and the ical Research Council, Dr. Dora Colebrook, has been inted by the Medical Research Council to work in the laboratories of Queen Charlotte's Hospital, Hammersmith, where a number of agglutinating sera are available typing puerperal strains of streptococci. Her appointment gives effect to a recommendation of the Departmental mittee on Maternal Mortality, that combined epidemiological and bacteriological investigation should be more undertaken, with a view to defining the responsibility he throat "carrier" and to investigating the rôle played other infective conditions in persons in contact with the nt. Dr. Colebrook's time will be fully occupied with al typing. Medical officers of health are invited to communicate directly with Dr. Colebrook in the event of n outbreak, and to send swabs from the cervix uteri or per vagina, and from tonsils and nose of the patient and the contacts. By this means it is hoped to determine the demiological nature of the infection and to trace its rce.

Naval Medical Compassionate Fund.

A meeting of the subscribers of this fund will be held at 3 P.M. on March 31st at the Medical Department of the Navy, Archway Block N., Admiralty, London, S.W. 1, to elect six directors of the fund.

Eugenics Society.

At a meeting of this society, to be held at 8.30 P.M. on Tuesday, March 15th, at the rooms of the Linnean Society, Burlington House, Piccadilly, W., Mr. J. Myles Bickerton will speak on Eugenics and Blindness.

Royal Statistical Society.

The *Frances Wood Memorial Prize*, value £30, is offered this year for the best investigation, on statistical lines, of any problem affecting the economic or social conditions of the wage-earning classes. Particulars may be had from the hon. secretaries of the Royal Statistical Society, 9, Adelphi-terrace, London, W.C. 2.

History of Pædiatrics.

Dr. G. F. Still will give a lecture on the Medical Care of the Child through the Ages, at 3 P.M. on Tuesday March 15th, at 31, Belgrave-square, London, S.W. The lecture will be in aid of King's College Hospital, and particulars will be found in our advertisement columns.

Course on Disorders of Digestion.

A course on the medical and hydrological treatment of diseases of the digestive tract, the liver, and of nutrition, will be held from April 18th to May 2nd at the Hôpital Necker, Paris, under the direction of Prof. Maurice Villaret. It will include a study tour to Vichy from April 30th onwards. Particulars may be had from the Laboratoire d'Hydrologie of the Faculté de Médecine de Paris (École pratique).

A Reduced Maternity Death-rate.

At Glasgow Royal Maternity and Women's Hospital last year the maternity death-rate was 2 per cent., as against 2·6 per cent. in the previous year. The number of abnormal cases was 62 per cent. of all admissions; in the previous year the percentage was 70

A Summer School of Individual Psychology.

The Individual Psychology Association will hold a summer school this year at Semmering, a beautiful pass in the mountains about two hours' railway journey from Vienna. The meeting will take place from June 26th to July 10th, and can be attended by English people at a reasonable cost, as the Association can obtain concessions in respect of quarters and fares for the congressists. Prospectuses and further information can be obtained from the Secretary, Mrs. Sofie Lazarsfeld, Sollergasse 16, Vienna, I.

London Fever Hospital.

At the annual meeting of this hospital recently Lord Ebury, the president, stated that there was a deficit of £2337 on the year's working, and that failure to obtain a good response to a renewed appeal "will inevitably mean closing this institution, which for 130 years has done such wonderful work, and is still necessary to the life of this great city."

Southport Hydropathic Hospital.

In 1931 the patients admitted numbered 433, of whom nearly 300 came under the general heading of rheumatism. Most of them were able to return home to resume their normal avocations. The next largest group of patients, numbering 120, were suffering from affections of the nervous system. In the great majority of sciatic cases relief has been secured promptly, and in many has been retained permanently.

British Health Resorts Association.

This newly formed association will hold a regional conference at Hastings during the coming week-end. After a banquet on Friday night, the proceedings will open on Saturday morning with a meeting at which Dr. W. G. Willoughby, president of the British Medical Association, will take the chair, and the speakers will include Dr. E. P. Poulton, Dr. R. A. Young, Dr. Leonard Findlay, Dr. Wilfred Harris, Dr. G. R. Bruce, Dr. Percy Lewis, Dr. J. R. Dingley, and Dr. Thomas Read. At a second meeting later in the day Lord Meston will preside, and brief addresses will be given, among others, by Lieut.-Colonel R. H. Elliot, Mr. Clough Williams-Ellis, and Dr. Fortescue Fox. Proposals will be made for the formation of a local branch of the association. On Sunday visits will be paid to Eastbourne, Bexhill and other resorts in the area. The address of the hon. secretary of the association is 6, Elsworthy-road, London, N.W.3.

as the result of inquiry, regarded as cases of post-vaccinal encephalitis, and 102 proved fatal. In the remaining five cases, of which two died, there appeared to be no reason to associate the encephalitis with the antecedent vaccination.

THURSDAY, FEB. 25TH.

Mental Deficients and Paternity Cases.

Sir JOHN HASLAM asked the Home Secretary whether his attention had been drawn to a recent paternity case tried at the Bolton county police-court, wherein a man who acknowledged his responsibility escaped his liability, because the justices had to dismiss the application owing to the claimant being of too weak an intellect to understand the nature of an oath; and whether he would introduce, at an early date, legislation to remedy that state of things.—Sir HERBERT SAMUEL replied: This case is most exceptional and probably unique. The complainant appears to have been of insufficient capacity to understand the nature of an oath or of the proceedings, and it would cause injustice if an order could be made against a man denying paternity without the evidence of the mother. In this case the man is reported to have been willing to admit paternity and, if so, the right course to pursue would be to invite him to enter into an enforceable agreement for the payment of maintenance to the mother.

Medical Benefit Regulations.

Dr. HILLMAN asked the Minister of Health whether, seeing that he had decided not to proceed with the proposed redraft of parts of the medical benefit regulations dealing with fee-charging, and that the Insurance Acts Committee of the British Medical Association acquiesced in this decision, he would take the opportunity of making it clear that there was no connexion between the proposed redraft and the deduction from insurance doctors' remuneration made as an emergency economy last October.—Sir E. HILTON YOUNG replied: I am glad to have an opportunity of repeating what I indicated in reply to a question on this subject by my hon. friend on Dec. 3rd, that the proposal to redraft the relevant parts of the regulations was initiated by the department in September, 1930, and was therefore entirely unconnected with the proposals for securing emergency economies in the cost of medical benefit which became necessary a year later.

Mr. RHYS DAVIES: Will the right hon. gentleman tell the House why the proposed draft has been dropped?

Sir E. HILTON YOUNG: It was dropped because it was considered not to be necessary.

Sanatorium Treatment of Tuberculosis.

Mr. DAVID GRENFELL asked the Minister of Health if he would give the most recent figures showing the result of treatment of tuberculous patients at sanatoriums in the United Kingdom, with the number of patients admitted, the number who were passed out as cured, and the number where treatment was unsuccessful.—Sir E. HILTON YOUNG replied: The following are the figures in respect of England and Wales: The number of persons admitted for the treatment of tuberculosis to approved residential institutions in England and Wales in the year 1930 was 44,517. The number of persons discharged in the same year from such institutions with their disease quiescent was 9410. The number who died in the institutions in the same year was 5073. A person who has suffered from tuberculosis is not considered to be cured of the disease until it has been quiescent for five years if it is pulmonary, or for three years if it is non-pulmonary. It is not therefore usually possible to say at the date of discharge from an institution whether the treatment has been permanently successful.

Milk and Butter-fat Standard.

Mr. GLOSSOP asked the Minister of Health whether in view of the fact that under the existing law milk might be sold containing less than 3 per cent. butter-fat, Government standard, provided that the farmer could prove that such milk was as it came from the cow, he would consider the revision of the law in this matter.

Brigadier-General CLIFTON BROWN asked the Minister of Health whether, seeing that the law did not require that milk shall contain any particular percentage of fat, and that it was not an offence to sell milk containing less than 3 per cent. of fat, he would alter the sale of milk regulations which lay down that milk containing less than 3 per cent. of fat was presumed to be adulterated until the contrary was proved; and whether he would put the onus of proof on the prosecutor as was the case in other similar regulations.—Sir E. HILTON YOUNG replied: I have received representations with regard to the amendment of the law in the directions suggested, and will consider the matter in consultation with my right hon. friend, the Minister of Agriculture and Fisheries.

Labelling of Imported Meat.

Mr. HURD asked the Minister of Agriculture what mea were taken to lead local authorities to enforce the distin labelling of imported meat in the shops, as required by th Sale of Food Order, 1921; and whether he was aware of th laxity of some authorities in this matter.—Sir Jo GILMOUR replied: As my hon. friend is no doubt aware, th Sale of Food Order of 1921 has now been revoked with th exception of the provisions relating to meat. This porti of the Order has been continued in force from year to ye under the Expiring Laws Continuance Act. Power enforce the provisions lies with the local authorities, a I have no power to compel them in the matter.

TUESDAY, MARCH 1ST.

Poison Gas Experiments on Animals.

Mr. GROVES asked the Financial Secretary to the War Of the reason why no reports had been issued on the work of chemical warfare medical committee since 1920 on question of poison gas experiments on animals; and wh accounts of the experiments performed during the last years and their results might be obtained.—Mr. D COOPER (Financial Secretary to the War Office) repli This committee was dissolved in 1919 and research on problems has been continued by the Chemical Defe Committee. Information as to the number of experime performed is given in the Home Office returns of exp ments on living animals of which the last issue was d July 29th, 1931.

Blindness and Insanity Due to War Service.

Mr. MCGOVERN asked the Secretary of State for the number of persons who were blinded and driven in as a result of service in the late war, and the numbers lost either an arm or a leg or both arms or both legs.—M TRYON (Minister of Pensions) replied: The approxi numbers of pensions in the categories mentioned at the of 1931 were as follows: Cases of total blindness, of mental disorder in mental hospitals, 6300; and cas amputation of a leg or arm, or of both arms or both 34,500.

Appointments

Certifying Surgeons under the Factory and Workshop ARNOTT, D., M.B., Ch.B. Edin. (Shaftesbury); SEARS, L.R.C.P. Lond., M.R.C.S. (Lyndhurst); and WORSLE (Malvern).

Births, Marriages, and Deat

BIRTHS.

HUBBLE.—On Feb. 24th, the wife of Douglas Hubble, M. Kedleston-road, Derby, of a daughter.

MCCURRICH.—On Feb. 23rd, at Palmeira-avenue, Hov wife of H. J. McCurrich, M.S., F.R.C.S., of a son (still

SWINDELL.—On Feb. 25th, at Westwood-road, Southam the wife of Dr. R. S. Swindell, of a daughter.

DEATHS.

ANDREWES.—On Feb. 24th, at Windy Gap, Merton-lane, gate, Sir Frederick William Andrewes, M.D., F.R.S., 73rd year.

APPERLY.—On Feb. 24th, suddenly of pneumonia, at Chas Kingswood, Surrey, Herbert Apperly, L.D.S. R.C.S

CATHCART.—On Feb. 22nd, at a nursing home, Edinb Charles W. Cathcart, F.R.C.S. Eng. and Edin Newbattle-terrace, Edinburgh.

GARDNER.—On Feb. 27th, at Imberway, Warminster. W Gardner, M.R.C.S., L.R.C.P., in his 75th year.

VAN GEYZEL.—On Feb. 20th, suddenly, at Hotel Beau Cannes, John Lawrence Van Geyzel, C.I.E., Colonel (retired), aged 74.

N.B.—A fee of 7s. 6d. is charged for the insertion of Noti Births, Marriages, and Deaths.

QUEEN'S INSTITUTE OF DISTRICT NURSI Princess Alice, Countess of Athlone, last week pres long service badges to "Queen's" superintendents nurses who have completed 21 years' service. Sinc last meeting of the council 32 associations have been affi and the names of 405 nurses have been placed on th of Queen's nurses. At the end of last year there deficit, and had it not been for the large sum raised b gardens scheme "the institution would have been with a very serious financial crisis."

NOTES, COMMENTS, AND ABSTRACTS

YOUTH AND THE CINEMA.

IE cinema makes its impression essentially upon eye, and the majority of people have a more itive memory for what they see than for what hear. Again, while the cinema affects people ll ages and all classes, it makes a particularly ig appeal to children and adolescents. Sir les Grant Robertson, speaking from the chair he National Conference on Problems connected the Cinema, held at the University of Birming- on Feb. 27th, said that within his lifetime four t developments of science—motor-cars, films, tion, and the wireless—had fundamentally altered lives of ordinary men and women. In his opinion most revolutionary of the four was the cinema, yet it was the only one left entirely without ernment control in this country. Sir Charles he made a practice of attending the cinema in company of young people, and he could not pe a sense of misgiving at the thought of a dy infiltration into their subconsciousness of the l of representation and criticism of life shown the films. Lady Barrett, M.D., emphasised this it when she quoted the answer of many children he time of the Birmingham inquiry as to what y learned from the pictures—"We learn what is really like." Everybody would agree, she l, that it was not a good thing for children, who no background with which to compare what y saw, to be introduced to an unworthy view of and to form the opinion that normal life was that. Lady Barrett dealt with the question of ental responsibility, and made an analogy with powers of a food controller. A mother might h to give her children food which was cheap and ich did not appear to her harmful, but a food troller would confiscate it because he understood danger of ptomaine poisoning. The average ther could not be expected to be an expert in chology any more than in toxicology, and we had much right to protect our children from poisoned nds as from poisoned bodies. Miss Cottell (Bristol), president of the National Union of Women achers, reminded the Conference that we have used to allow parents unlimited responsibility in ler matters, such as whether their children shall end school, or whether they shall engage in street iding, and there was reason to believe that children quired some protection in the matter of attendance films. As a teacher, she found that children's licacy of taste was vitiated by over-sensationalism d over-sentimentality of the cinema. Mr. J. wat Fraser, M.P., in his work among young delin- ients, had found undoubted evidence that the nema encouraged a tendency to youthful offences. r. W. A. Potts pleaded for improvement of the nema in the interest of adolescent boys and girls. e attended the pictures regularly once a week to e for himself the effect of the films on the minds l young people. As a medical practitioner, as a sychologist, and as a father, he felt bound to protest gainst scenes which appeared to be staged with a eliberate intention to stimulate the sex instinct. ife at the threshold of manhood and womanhood as difficult enough without adding to the burden temptation.

Throughout the day a large amount of evidence as forthcoming as to a widespread dissatisfaction ith the conduct of the cinema, and a real desire or its amendment. Only one resolution was on the genda, and after much discussion it was passed in the following form: "That this Conference submits that a comprehensive inquiry into the arrangements by which films are licensed for public exhibition is urgently called for, and asks the Home Secretary to receive a deputation on this subject."

THE SCIENCE OF MEDICINE.

THE author of this book, whose full title is "The Science of Medicine: How Chronic Diseases are Cured Medicinally by Raphael Roche,"[1] informs us that he has received great commendation in the lay press, that he has made communications himself to that press on the science of medicine, and that the book is submitted as the fruit of over half a century of practice. He deprecates estimates of his medicinal cures, if formed on the fact that he employs (in his own words) "drugs in such an extreme dilution that no analysis, chemical or spectroscopic, will discover their existence"; but from instructed therapeutists he must expect such criticism. He refers to "the emphasis I lay on unusual symptoms, which may sound like affectation"; the instructed physician or surgeon knows that the unusual symptom is often the revealing one and could never find fault with the intention to detect it though he might wonder whence the diagnostic skill is derived. Attention is drawn on the cover to the fact that the work contains a full statement by Mr. Bernard Shaw of his medicinal cure by the author; the instructed doctor will here find some odd logic. The author and Mr. Reginald Dingle, who is thanked for his help in writing the book, have produced an indictment which will give pleasure to all who are "agin the doctor," and which may attract the public to the consulting room of Mr. Roche, whose fees we learn from himself, "are so much higher than those of any legally qualified physician." Of *how* diseases are cured there is nothing intelligible said; but there are allusions to Vital Force.

PSYCHOLOGY IN INDUSTRY.

IT is gratifying in these days to learn of one industrial body that has experienced no decline in its activities. The eleventh report of the National Institute of Industrial Psychology describes 32 investigations in factories, shops, and offices. Whereas in the past attention has chiefly been centred on problems of production, it seems probable that the future may see the same intense thought and activity applied to problems of distribution; the selection and training of salesmen, the display of goods, market research, and sales organisation. As examples of the Institute's work may be cited a demonstration of the superiority of hand-packing over conveyor packing in a chocolate factory, whereby a saving of £2000 a year was effected; and the reorganisation planned for a patent flour factory which will save £3700 a year on an initial outlay of £7000. Further investigations have been carried out for the Post Office; tests have been devised for phonogram and teleprinter candidates; and various forms, previously misunderstood by many recipients, have been redrafted to save correspondence and explanation. During 1931 the Institute enrolled 284 new members and received more than 7000 visitors, including the Prince of Wales. Public demonstrations are given on the last Wednesday in each month, and on at least one Saturday morning, when films are shown and methods demonstrated. The Journal has become so popular that it is to appear monthly instead of quarterly, under the title of *The Human Factor*, and early in 1932 a popular survey ("Industrial Psychology in Practice") and a history of the Institute ("Ten Years of Industrial Psychology") are to be published.

The vocational guidance department advised 500 young people during the year under review, and the cases examined in 1927 and 1928 have been followed up by a questionaire. Of 90 people working in accordance or apparently in accordance with the Institute's advice, 76 were found to be successful

ADDRESSES AND ORIGINAL ARTICLES

THE PATHOLOGY AND TREATMENT OF ANÆMIA.

BY L. J. WITTS, M.D. MANCH., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO GUY'S HOSPITAL; WILL EDMONDS CLINICAL RESEARCH FELLOW.

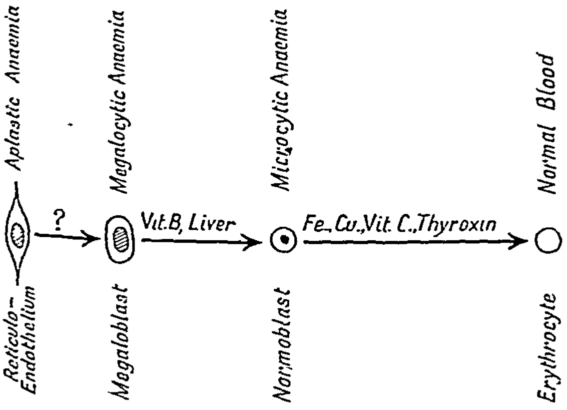
LECTURE II.

THE ANHÆMOPOIETIC ANÆMIAS.*

> "The volume of blood depends on the quantity of nutriment dissolved and absorbed by the digestive tract."
>
> SAMUEL FENWICK, "Atrophy of the Stomach," 1880.

IN this second lecture I propose to discuss the anæmias which result from disturbances of nutrition and disorders of the alimentary tract. They form a group which impresses both by its size and its unity. It is my opinion that all are of nutritional origin. The normal human diet contains substances which are necessary for the maturation of megaloblast into normoblast, such as vitamin B and the active principle of liver, and others which are necessary for the maturation of normoblast into erythrocyte, such as vitamin C, thyroxin, iron, and traces of other minerals. Animal experiments [16] suggest that food substances are also necessary for the development of the megaloblasts from the reticulo-endothelium of the marrow, and that their absence leads to aplasia. Anæmia arises whether these substances are not supplied with the diet or whether they are not absorbed in digestion.

FIG. 1.



Scheme of anhæmopoietic anæmias showing point of action of the substances essential for blood formation.

The anæmia is due to diminished blood formation or anhæmopoiesis, and according to the level at which hæmopoiesis is arrested, the marrow may be normoblastic, megaloblastic, or aplastic. The cells drafted into the circulation from this dysplastic marrow are sometimes abnormal and liable to early destruction, but hæmolysis is always secondary to the degeneration of the bone-marrow, and is never of high degree. The reticulocyte count is low, the resistance to hypotonic saline is little impaired, and hæmoglobinæmia and hæmoglobinuria never occur. The white cells and the platelets are normal or diminished. Remission of the disease is attended by an outpouring of reticulocytes in numbers directly proportional to the extent of the hyperplasia of the bone-marrow. All these features are in direct contrast to the hæmolytic anæmias, which will be described in the next lecture. Clinically these anæmias are characterised by their frequent association with glossitis, gastro-intestinal disorders, and degeneration of the nervous system.

Some of these anæmias are simple and uncomplicated: the nutritional anæmia of infancy is entirely due to shortage of minerals in the milk, and the anæmia of scurvy to shortage of vitamin C. In others the effects of one deficiency predominate in the blood picture, but traces of other defects may be recognised, as when iron deficiency occurs in Addison's anæmia,[5] or of the liver principle in simple achlorhydric anæmia.[14] In other cases, again, the symptoms of multiple deficiency may be present together, as in the anæmia of pellagra or in tropical macrocytic anæmia. The blood picture may change during the evolution of the primary disease. Megalocytic anæmia is very constant in Addison's anæmia, but it is not uncommon for the disease to begin as a microcytic anæmia, and more rarely it terminates in aplasia. This sequence of events is almost the rule in sprue.

Anæmia from Defective Nutrition.

The divisions I have made of this group of nutritional and alimentary anæmias are for convenience of presentation, for it is clear that nutritional defects may lead to disease of the alimentary tract, and that alimentary disease may lead to ingestion of an imperfect diet, either from appetite or from prescription. For brevity I shall use the terms hypochromic, orthochromic, and hyperchromic for anæmias in which the colour-index is below unity, unity, and above unity respectively.

Nutritional anæmia of infants.—Anæmia of moderate degree is present in practically all infants, whether fed by the breast or artificially. It may become very severe, especially in twins and premature babies, who come into the world with a small store of iron, or after intercurrent infection, or when suckling is protracted beyond the normal period. It disappears spontaneously on the adoption of a mixed diet. Helen Mackay has made a comprehensive and illuminating study of this anæmia, which appears to be a pure mineral deficiency, resultant from the low iron and mineral content of the milk and reparable by inorganic salts of iron.

The anæmia of scurvy.—Mettier and co-workers have recently discussed the anæmia of scurvy and have shown that severe hypochromic anæmia is often present in cases where no bleeding has occurred. The bone-marrow is moderately hyperplastic. The anæmia does not respond to iron, or to liver extract which has been deprived of its vitamin C (though still effective in pernicious anæmia), but there is a prompt response of reticulocytes and rapid regeneration of the blood on administering foods which are rich in vitamin C. They suggest that when vitamin C has been chronically deficient its replenishment promotes the development of the nucleated erythrocytes, and so permits a reticulocyte response and repair of the anæmia.

---

* The second Goulstonian Lecture for 1932, delivered before the Royal College of Physicians of London on March 3rd. Lecture I. appeared last week.

and only eight definitely unsuccessful. Of 44 who did not seem to have taken the advice, 17 were successful and 17 unsuccessful, with ten doubtful. This department is also working among Borstal lads. A great deal of research is being done in the vocational department as well as along more general lines. The work of secretaries and nurses is being analysed; the nature and measurement of the mental abilities involved in factory assembly operations have been investigated; experiments in typewriting have shown the great importance of rhythm in developing speed; and occupational conditions among the blind have been studied. More and more the Institute is making itself an essential and integral part of the industrial life of the nation.

INCUNABULA IN THE R.C.S. LIBRARY.

Mr. W. R. le Fanu, librarian to the Royal College of Surgeons of England, has compiled a list of the Incunabula in the College library [1] containing over fifty valuable items, but the experienced reader's eye will linger over three or four jewels. There is Benevenuto Grassi's De Oculis, 1474, recently translated by Casey A. Wood; John of Gaddesden's Rosa Anglica; Petrus de Abano's Conciliator differentiarum philosophorum et medicorum, &c., 1476; and Michael Scotus's Liber Physionomiæ, 1490. Osler wrote of Michael Scot as one of the greatest thirteenth century scholars, with whose observations on the temperaments and on the significance of dreams in persons of different complexions Freud and the modern advocates of incubation sleep would sympathise. It might be hoped that some day the breath of life which animates the museum below might stir the library to demonstrate its treasures to a wider circle.

TREATMENT OF RHEUMATOID ARTHRITIS.

We are informed by the Anglo-French Drug Co., Ltd. (238A, Gray's Inn-road, London, W.C.), that they hold stocks of Allochrysine, the gold compound mentioned by Dr. Jacques Forestier in his paper on rheumatoid arthritis in our last issue.

Vacancies

For further information refer to the advertisement columns.

Aberdeen City District Asylum, Newmachar.—Jun. Asst. P. £300.

Abergavenny, Monmouthshire Mental Hospital.—Jun. Asst. M.O. £350.

Ascot, Heatherwood Hospital for Orthopædic Children.—Res. Med. Supt. £850.

Aylesbury, Royal Buckinghamshire Hospital.—Res. M.O. £200.

Applications should reach the Private Secre Home Office, Whitehall, London, S.W., not later March 23rd.

---

[1] Reprint from Annals of Medical History, N.S. vol. ii., pp. 674–76.

why the blood picture may be normal in patients with achlorhydria, while a megalocytic anæmia may develop in patients with hydrochloric acid in the gastric secretion.

The mere absence of acid seems to play little part n the development of glossitis, megalocytic anæmia, or subacute combined degeneration of the cord. Physiologists[10] have long been sceptical of the antiseptic action attributed to the gastric juice, on which depended the theory that pernicious anæmia was due o hæmolysis by toxins elaborated by organisms in he alimentary tract, and much clinical evidence is at variance with this theory. To the hæmatologist he chief function of the gastric hydrochloric acid is o dissolve the mineral elements of the diet, while he ferments are infinitely more important in Addionian anæmia. It is conceivable that bacteria and parasites in the alimentary canal may destroy the hæmatinic principles of the food by their metabolic activities, and so indirectly influence the erythron. When we consider the intestinal diseases, we shall see that the secretion of hydrochloric acid by the stomach may be normal in cases where we have most reason to suspect this process, and we shall see that t often happens that the intestinal disease starts first and achlorhydria develops later. Intestinal infection cannot account for the fact that predigested liver is ten times as effective as raw liver in pernicious anæmia.[50] The natural conclusion from the evidence is that pernicious anæmia is the result of impaired gastric digestion and the consequent impoverishment of the plasma in the building stones for erythropoiesis.

Yet the gastrogenous theory of pernicious anæmia cannot be accepted without qualification. It is true that pernicious anæmia has developed in so many patients after operations on the stomach that we hardly need to postulate any inborn weakness of the hæmopoietic system for its development. Nevertheless, good health may be maintained for years without a stomach. In experimental animals removal of the whole stomach produces no glossitis, stomatitis, or nervous symptoms; anæmia occurs rarely, it is of the secondary type, and it is usually attributable to some additional strain such as pregnancy or diarrhœa.[31] Few human patients survive a complete resection of the stomach for very long, as the operation is seldom performed except for carcinoma, and death from metastasis occurs within two years. Of the 34 cases collected by Uhlhorn in 1927 only four were known to have survived longer than two years, and only one longer than four years. Nevertheless, all had lived some weeks or months after the operation, and there was only one doubtful instance of pernicious anæmia in the whole series (Moynihan's case, which was probably not pernicious anæmia [30]). When pernicious anæmia develops after subtotal gastrectomy, the interval of time is often more than five years, and it has been as long as 16 years.

It seems as if the human organism, like the animal, can compensate over long periods for the absence of the stomach. The final breakdown may be due to exhaustion of the hæmatinic reserves, the growth of an abnormal intestinal flora, or the failure of intestinal digestion. Those who cling to the old theory of intestinal infection in pernicious anæmia may think that the deciding factor is the intestinal flora, but when we consider the frequency of megalocytic anæmia in fatty diarrhœa and after intestinal resection, we shall probably conclude that it is a matter of the efficiency of digestion and assimilation in the intestine. While the results of gastrectomy show that a healthy intestine can compensate for the failure or absence of the stomach, there is evidence on the other hand that disorders of the intestine may nullify the effects of perfect digestion in the stomach. We seem driven to the view that in pernicious anæmia either gastric or intestinal digestion, or both, may be at fault.

Barnett has described an atypical case of pernicious anæmia, in which it seemed probable that intestinal absorption was at fault. The blood was typical of Addison's anæmia, but there was a good secretion of free HCl by the stomach. The anæmia responded to liver treatment. Nevertheless, Barnett was able to show that the gastric juice contained the "intrinsic factor" by carefully controlled experiments, in which another patient with pernicious anæmia was treated with beef muscle predigested in the juice.

Before leaving the subject of pernicious anæmia we may mention several points in which it differs from other megalocytic anæmias. These are: (1) the primitive character of the megaloblasts sometimes present; (2) the high degree of bilirubinæmia, bilirubin excretion, and hæmosiderosis; (3) the hypersegmentation of the polymorphonuclear cells. Much has been made of these differences by some hæmatologists, but the accumulation of knowledge has convinced the majority that the changes in pernicious anæmia shade indefinitely into those of other megalocytic anæmias. It is characteristic of pernicious anæmia that nutrition is well maintained. Apart from the subacute combined degeneration of the spinal cord, there is a pure and uncomplicated absence of the hæmatinic principle necessary for the maturation of megaloblasts into normoblasts. We should therefore expect in pernicious anæmia the most striking effects of megaloblastic degeneration of the bone-marrow, uncomplicated by the disturbances of the general health and of the iron and pigment metabolism, which accompany other alimentary and nutritional diseases. It is for this reason that the bilirubin excretion is so much higher and the megaloblasts so primitive. As regards the bone-marrow it may be noted that a thorough examination always reveals some areas of complete aplasia, though the majority of the bones contain hyperplastic marrow.

Simple Achlorhydric Anæmia and Allied Anæmias.

The new work on pernicious anæmia and its specific treatment with liver has caused a revival of interest in a form of anæmia in many ways related to pernicious anæmia, but differing from it in its unresponsiveness to liver and its curability by iron.[72] In this anæmia, which occurs almost exclusively in women, the colour-index is low and van den Bergh's reaction negative. It resembles pernicious anæmia in its association with achlorhydria—80 per cent. of my large series of cases—splenomegaly, and glossitis. It differs from it in the absence of degenerative changes in the spinal cord and in the presence in some cases of dysphagia, due to a backward spread of the inflammation of the mouth and tongue to the pharynx, a phenomenon rare in pernicious anæmia, though well known in tropical nutritional anæmia, sprue, and pellagra. Not a great deal is known of the morbid anatomy, but there appears to be a moderate normoblastic hyperplasia of the bone-marrow, a simple hyperplasia of the spleen, and no change in the other organs. The red cells are usually smaller than normal, and very deficient in hæmoglobin. Treatment with iron salts repairs the anæmia, and the red cells return to their normal size and hæmoglobin content.

TROPICAL NUTRITIONAL ANÆMIA.

Apart from the anæmia of infants fed on milk alone, defective diet is rarely responsible for anæmia in the temperate zones, though Minot[46] and others[34] have reported cases of anæmia of a megalocytic type which appeared to be due to prolonged restriction of diet, and which responded to treatment with liver. It is far otherwise in the tropical and subtropical zones, and in India, Africa, and China, a large fraction of the population maintains life on diets which are incredibly poor by western standards and which contain insufficient material for normal erythropoiesis. They are lacking in total calories, in protein, especially animal protein, in vitamins, and in mineral salts. Wills and co-workers have shown that the level of the blood count in various classes in India is directly proportional to the level of nutrition, and that malaria, hookworms, and similar anæmising influences can be ruled out of question in many instances. The anæmia is referable to dietetic defects alone, and it is often associated with skeletal deformities and œdema of a nutritional type. It is more common in women than men, and it may be hypochromic, orthochromic, or hyperchromic.

A striking feature of the anæmia is its tendency to assume a profound degree and a megalocytic type in pregnancy, though other influences may produce a similar aggravation, in men as in women. Indeed, the common occurrence of severe and often fatal megalocytic anæmia in pregnancy in Indian women first attracted attention to these anæmias. Medical advice is rarely sought before the last months of pregnancy when the patient is already profoundly anæmic. Fever, diarrhœa, and vomiting are marked symptoms, and the disease is more common in the second half of the year when diarrhœa is common. The tongue may be sore, and occasionally burning sensations pass down the fauces. The test-meal is normal, and there are no cord changes. The average red cell count is below a million, the mean diameter of the cells is increased, the colour-index well above unity. There is no jaundice or hyperbilirubinæmia, reticulocytes and nucleated red cells are infrequent, and normoblasts are more common than megaloblasts. The white cells are normal. If no treatment is given death occurs in about 40 per cent. of cases; post mortem there is hæmosiderosis of the liver and spleen, and aplasia of the marrow alternating with areas of megaloblastic hyperplasia.[4] If recovery occurs without treatment, or if treatment is insufficiently prolonged after confinement, the patient recovers to a certain extent, and then remains with a moderate anæmia, often of low colour-index. In the megalocytic phase the anæmia can be successfully treated not only with liver, but with marmite, a yeast extract rich in vitamin B. With either remedy there is a reticulocyte crisis and rapid improvement in the blood. Liver is rich in vitamin B, and it is probable that the curative effect of liver and marmite in tropical macrocytic anæmia should be ascribed to the vitamin B. Vitamin B is of no value in true Addison's anæmia,[13] and close as is the resemblance between tropical macrocytic anæmia and Addison's anæmia, they are undoubtedly due to different defects. The needs of the erythron are complex. For the maturation of normoblasts into erythrocytes, we already know that iron, thyroxin, and vitamin C are essential; for the maturation of megaloblasts into normoblasts, vitamin B and the nitrogenous complex of liver which is effective in Addison's anæmia.

It is important to remember that similar exacerbations of the anæmia occur in males and in non-pregnant women. There is no sign of hæmolysis, and the disease is quite different from the rare hæmolytic anæmia of pregnancy of the temperate zones. On the other hand, the very large number of cases of "pernicious anæmia of pregnancy" which have been described in the southern States of the U.S.A. seem to belong to this same nutritional, anhæmopoietic group. They are characterised by similar symptoms, glossitis, gastro-intestinal disturbances, incomplete repair of the anæmia after pregnancy, and a strong tendency to recurrence in subsequent pregnancies, and the diet seems to be very faulty.[2 48 60 61] Here also most probably belong some of the cases diagnosed as sprue without diarrhœa, in which severe anæmia develops during pregnancy.[28 36] Tropical nutritional anæmia has been extensively studied in China by Keefer and co-workers, who have found that it can be most effectively treated by a combination of liver and iron. It is indeed obvious from descriptions of the diets that there must be deficiency of several of the principles necessary for blood formation.

Pernicious Anæmia.

Pernicious anæmia has been so much discussed in recent years that the main facts can be briefly summarised. Addison's classical account was supplemented by precise descriptions of the blood and the blood-forming organs by Ehrlich and his pupils, while other continental workers demonstrated the increase in bilirubin in the blood and the excretions. Price-Jones showed that the megaloblastic degeneration of the bone-marrow was associated with an increase in the mean diameter of the erythrocytes and the presence of megalocytes in the circulation Hurst and co-workers demonstrated the essentia unity of Addison's anæmia and subacute combine degeneration of the spinal cord, and proved tha achlorhydria was the rule in both conditions. Typica Addison's anæmia was cured by restoration of th gastric secretion, either spontaneously or afte removal of septic foci and lavage,[12 30] while in significant number of cases Addison's anæmi developed after operations on the stomach.[31] Th Boston school of hæmatology, in one of the mos beautiful researches in the history of medicin showed that liver, stomach, and kidneys contain principle curative in pernicious anæmia, and tha this principle is normally elaborated in digestion b the stomach and stored in the liver and kidneys.[11]

The gastrogenous theory of pernicious anæmia founded on a firm basis of fact. The essence of th theory is that the stomach contains a rennin-lik ferment, which is not hydrochloric acid, nor pepsi nor rennin, and that this "intrinsic factor" acts o the proteins of the food to produce a hæmatin principle, which is necessary for the maturation megaloblasts into normoblasts and the norm delivery of red cells into the circulation. The hæm tinic principle is more active parenterally than b mouth, and it is almost certain that it acts directl on the erythron, and not on the alimentary tract the organisms contained therein. Its action is t stimulate the production of red cells and not to chec hypothetical hæmolysis. The discovery of th intrinsic factor of the stomach has solved many the problems of pernicious anæmia. The secretio of acid, pepsin, and intrinsic factor need not ru parallel. The intrinsic factor may be present i cases of anacidity, and it may be absent with a fr secretion of hydrochloric acid. It is thus explaine is associated with malabsorption of fat, and should be compared with the anæmia of chylous diarrhœa, sprue, and gastro-colic fistula. Achlorhydria is usually present. Again, the problem is whether achlorhydria precedes intestinal ulceration, the sequence being achlorhydria→intestinal ulceration→resection→anæmia, or whether, as seems more probable from the analogy of other fatty diarrhœas, achlorhydria and anæmia are the result of the intestinal resection and fatty diarrhœa. The anæmia may be simple or pernicious in type.

Becker (1030) describes the case of a 29-year-old woman who was operated on for tuberculous stenosis in several parts of the lower small intestine. At the time of the operation she did not show any remarkable paleness. Over 2 metres of the small intestine and the first part of the cæcum were removed, and she was freed from the stenosis troubles. Two months after the operation she began to notice œdemata and to feel tired. When five months after the operation she was taken to the hospital, she had a typical pernicious anæmia. The œdemata were quite large. On treatment with liver, there was a reticulocyte crisis and rapid improvement. The œdemata diminished but did not disappear. The patient was then taken ill with a double-sided otitis and erysipelas. She died in septicæmia. Post mortem it was established that a stenosis no longer existed.

Saltzman has reported a similar case in a woman of 28, who first came under treatment four years after the resection of 222 cm. of jejunum. She now had pernicious anæmia with achylia, which followed the usual remittent course and which responded to liver.

Adamson and Smith observed "chronic chlorosis" in a man several years after the resection of 4 feet of small bowel.

INTESTINAL STENOSIS.

The association of pernicious anæmia with intestinal stenosis has been known for many years, and Meulengracht was able to collect accounts of 20 cases in 1929.[43] The strictures are usually tuberculous, and involve the lower part of the small intestine, occasionally the upper part of the colon. The tongue, the nervous symptoms, the blood, and the bone-marrow are all typical of pernicious anæmia. In Meulengracht's cases complete achylia was demonstrated in every case on which a test-meal was done; in one of his cases the test-meal was normal six years before the anæmia developed, but achlorhydria was present when the anæmia was detected. Becker (1930), Little, and A. F. Hurst (personal communication) have since described cases in which there was a normal secretion of hydrochloric acid. Thus achlorhydria is not an integral part of the disease, and it may be the result of the intestinal stricture. The anæmia responds to liver treatment with a reticulocyte crisis and prompt regeneration of the blood.[7 37 43 63] Seyderhelm's patient recovered without other treatment when the stricture was resected. Little's patient relapsed on omitting liver after the normal anatomy of the intestine had been restored, but diarrhœa was still present, and the normal function of the intestine had obviously not been regained.

The coexistence of such rare conditions as pernicious anæmia and intestinal stenosis points to an ætiological connexion, which was proved when Seyderhelm produced pernicious anæmia in two out of ten dogs by ligating the small intestine. He showed that the onset of anæmia was more closely related to the growth of an abnormal intestinal flora than to the degree of narrowing of the gut. He suggested that pernicious anæmia was due to the absorption of bacterial poisons from the intestine, that their growth was favoured by achylia, and that their absorption was due to abnormal permeability of the intestinal wall. There is no evidence that toxins are absorbed or circulate in pernicious anæmia, or that toxins can produce pernicious anæmia. It is simpler to assume that if the intestinal bacteria play a part, it is either the destruction of the hæmatinic principles of the food by their metabolic activities, or the impairment of digestion and assimilation by their local effects on the mucosa of the stomach and intestine. In conclusion, I should like to point out that the anæmia of intestinal stenosis is not always, and perhaps not most frequently, of the megalocytic type, for a hypochromic anæmia may develop in simple stenosis of the intestine, where there is no hæmorrhage or gross infection and toxæmia.

Miss A had operations for tuberculous glands in the neck and the mesentery at the age of 14. In adolescence she suffered from bilious attacks for which her gall-bladder and appendix were removed without benefit. At the age of 20 she was found to have chronic duodenal stasis, ileal stasis, and calcified abdominal lymph glands; the test-meal was normal, and the hæmoglobin 85 per cent. At the age of 22 she had definite obstruction of the terminal loop of the ileum, which was dilated, half full of gas, and lifted out of the pelvis; there was no occult bleeding; the blood count was: red cells, 3,880,000 per c.mm.; white cells, 8000; Hb., 64 per cent.; colour-index, 0·83. She was treated by Dr. Hurst with a low-residue diet, belladonna, liquid paraffin, and grs. 75 of iron and ammonium citrate a day, and two years later her symptoms were much better, the obstruction had diminished, and the hæmoglobin was 87 per cent.

A man, aged about 40, was readmitted to Guy's Hospital six months after an operation for strangulated hernia. He now had a stricture of the ileum and a moderate hypochromic anæmia. He succumbed to the operation for the relief of the stricture, and I found normoblastic hyperplasia of the bone-marrow in the centre of the humerus.

INTESTINAL PARASITES.

Much of the literature of the association of pernicious anæmia with intestinal parasites is uncritical, and the subject is worthy of careful review by one interested in hæmatology and parasitology. Many intestinal parasites have been reported in association with pernicious anæmia, but the only one which occurs with any frequency is *Dibothriocephalus latus*. Even so, pernicious anæmia from *D. latus* infestation is rare, and it has been calculated that in Finland, where many are infested with this worm, only from 0·1 to 0·5 per cent. of those infested develop anæmia. It also appears that the victims of *D. latus* anæmia are often predisposed to pernicious anæmia by heredity or by achlorhydria. Achlorhydria occurs in over 80 per cent. of cases, but it is sometimes the result of the disease, and free acid may return when the worm is expelled.[45 69] *D. latus* anæmia is of great interest, inasmuch as it may be repaired either by expulsion of the worm or by treatment with liver. Expulsion brings about a complete cure, while liver merely repairs the anæmia, which will relapse if liver is discontinued, and the parasite allowed to remain.[7] Many attempts have been made to explain *D. latus* anæmia by the liberation of hæmolysins from the parasite, but opinion is now changing to the view that it depends on the destruction of the hæmatinic principles of the food by the parasite, or diminished intestinal absorption.

GASTRO-INTESTINAL ULCERATION.

Many instances have been reported of pernicious anæmia in association with cancer of the stomach,[59] dysentery, and tuberculous ulceration of the bowel.[32] Complex factors are at work in these cases, such as achylia, intestinal dyspepsia, hæmorrhage, toxæmia, and defective diet, but the anæmia may respond well, and with the typical reticulocyte crisis, to treatment with liver.

Fatty Diarrhœa.

Donald Hunter has described the disturbances in the metabolism of calcium and phosphorus which

There is reliable evidence that the anæmia is due to shortage of iron, caused partly by improper food and partly by defective absorption from the alimentary canal. Iron is best absorbed from an acid medium, which explains the significance of achlorhydria. In those who have normal gastric secretion there are usually symptoms of intestinal dyspepsia. Anæmia is not uncommon in chronic abdominal invalids as a result of their restricted diet and poor digestion. Lyon estimated the hæmoglobin in 100 women with uncomplicated retroversion of the uterus, confirmed by operation, and found a third with only 70 per cent. or less hæmoglobin. This microcytic anæmia is practically confined to the reproductive epoch, and it is much aggravated by pregnancy. It persists with varying intensity throughout the child-bearing period, and then tends to improve spontaneously after the menopause. Seven women whom I have treated by the induction of an artificial menopause have all done well and remained free from relapse. Seppänen has clearly shown that women are more liable to anæmia than men, and the sex-incidence of simple achlorhydric anæmia can be explained by the greater frequency of achlorhydria and chronic abdominal invalidism in women, and by the strain of their reproductive life.

We have been specially interested in the gastric secretion in these cases of achlorhydria and anæmia. Until lately it seemed inexplicable why achlorhydria should sometimes be associated with perfect health, at other times with a microcytic anæmia, and at others with a megalocytic anæmia. Whether microcytic anæmia develops or not seems purely a matter of the iron metabolism. The normal diet provides only a small positive balance of iron, especially for women who are menstruating and bearing children, and this soon becomes a deficit if the diet is poor and absorption is diminished by achlorhydria. For the explanation of the megalocytic anæmia we are indebted to Castle's brilliant hypothesis. S. J. Hartfall and I have found that the subcutaneous injection of histamine into patients with simple achlorhydric anæmia or with pernicious anæmia induces a small secretion of gastric juice, and that in simple achlorhydric anæmia this juice may be as deficient in acid and pepsin as in pernicious anæmia. To ordinary tests they are identical. Nevertheless, on incubating beef with juice from simple achlorhydric anæmia, we obtained the curative principle for pernicious anæmia. We found that beef incubated with the gastric juice of a patient with pernicious anæmia produces no effect. Beef incubated with the gastric juice of a patient with simple achlorhydric anæmia usually causes a small reticulocyte crisis. Beef incubated with normal gastric juice is approximately as effective as an equivalent amount of liver. Thus the gastric juice in simple achlorhydric anæmia, and in patients who are normal except for achlorhydria,[11] contains Castle's intrinsic factor and protects the individual from pernicious anæmia.

In pernicious anæmia the damage to the gastric mucosa is higher in degree or different in kind from simple achlorhydric anæmia. The secretions usually fail in the order HCl, pepsin, intrinsic factor, but in rare cases the intrinsic factor may disappear and pernicious anæmia develop though acid and pepsin are conserved. A case may begin as simple achlorhydric anæmia and later pass into pernicious anæmia, because the secretion of HCl and intrinsic factor is successively exhausted. Partial recovery may occur and the pernicious anæmia give place to simple achlorhydric anæmia with the return of the intrinsic factor, HCl remaining suppressed. Members of families where a vulnerable gastric mucosa is inherited may differ in their response to the wear and tear of life, some developing pernicious anæmia from the complete failure of the gastric mucosa, others simple achlorhydric anæmia or a symptomless achlorhydria from its partial failure. Finally, we can understand how the digestion of the food may be perfect and yet anæmia develops owing to defective absorption from the intestine, and so a megalocytic anæmia may develop in spite of the presence of intrinsic factor in the stomach, or—much more commonly—the microcytic anæmia of iron deficiency develops in spite of a normal secretion of hydrochloric acid. Here we must leave Castle's hypothesis for further testing—and in my opinion for a certain modification—in the future.

Diseases of the Intestines.

In the study of anæmia in intestinal disease we are faced with more intricate problems than in the nutritional and gastrogenous anæmias. In addition to the intestinal disease there may be an imperfect diet and an impaired gastric digestion. The frequency of achlorhydria and glossitis in intestinal disease is remarkable. It is often assumed that this achlorhydria is primary, but while achlorhydria may favour infection of the intestine, we have unimpeachable evidence that achlorhydria may be the result of disease of the intestines, developing during the evolution of the illness, and often giving place to normal secretion on its cure, as I shall show when we consider intestinal stenosis, tapeworm infestation, sprue, and chylous diarrhœa. The mechanism of this action on the stomach is obscure. Morbid changes in the intestine may spread directly to the stomach, or irritant or infective material may ascend by reverse peristalsis. Lycopodium spores or other finely divided and easily recognisable material given in enemata can travel in a few hours from the rectum to the stomach, and lycopodium powder swallowed in sealed capsules may later be recovered from the mouth.[3] There is no difficulty about the mechanism of this process but it presumes an unknown irritant. There is less difficulty in supposing that nutritional disorders of a pellagroid type develop when absorption from the intestine is diminished by disease, with consequent glossitis and achlorhydria.

Another problem in the intestinal anæmias is the relative importance of disease of the stomach and of the intestine in their production. Is the usual sequence of events intestinal disease→gastric disease→anæmia, or do both stomach and intestine play a part in the anæmia? Estimation of the acidity of the contents of the stomach does not help us, and we shall not solve the problem until a simpler technique has been devised for the detection of the intrinsic factor of Castle in the stomach. We shall do well not to underestimate the intestinal factor, for Barnett's important case, which I have already quoted, shows that a megalocytic anæmia may develop in spite of the secretion of the intrinsic factor by the stomach.

RESECTION OF THE SMALL INTESTINE.

Resection of the small intestine, usually done on account of tuberculosis, provides the simplest examples of anæmia from intestinal disease. The literature [58] contains records of more than 90 patients who have survived the loss of over 2 metres of small bowel. There is little information about their state of health, though it is clear that they often suffer from diarrhœa and debility. The following three cases suggest that anæmia is a common sequel. It is associated with malabsorption of fat, and should be compared with the anæmia of chylous diarrhœa, sprue, and gastro-colic fistula. Achlorhydria is usually present. Again, the problem is whether achlorhydria precedes intestinal ulceration, the sequence being achlorhydria→intestinal ulceration→resection→anæmia, or whether, as seems more probable from the analogy of other fatty diarrhœas, achlorhydria and anæmia are the result of the intestinal resection and fatty diarrhœa. The anæmia may be simple or pernicious in type.

Becker (1930) describes the case of a 29-year-old woman who was operated on for tuberculous stenosis in several parts of the lower small intestine. At the time of the operation she did not show any remarkable paleness. Over 2 metres of the small intestine and the first part of the cæcum were removed, and she was freed from the stenosis troubles. Two months after the operation she began to notice œdemata and to feel tired. When five months after the operation she was taken to the hospital, she had a typical pernicious anæmia. The œdemata were quite large. On treatment with liver, there was a reticulocyte crisis and rapid improvement. The œdemata diminished but did not disappear. The patient was then taken ill with a double-sided otitis and erysipelas. She died in septicæmia. Post mortem it was established that a stenosis no longer existed.

Saltzman has reported a similar case in a woman of 28, who first came under treatment four years after the resection of 222 cm. of jejunum. She now had pernicious anæmia with achylia, which followed the usual remittent course and which responded to liver.

Adamson and Smith observed "chronic chlorosis" in a man several years after the resection of 4 feet of small bowel.

INTESTINAL STENOSIS.

The association of pernicious anæmia with intestinal stenosis has been known for many years, and Meulengracht was able to collect accounts of 20 cases in 1929.[43] The strictures are usually tuberculous, and involve the lower part of the small intestine, occasionally the upper part of the colon. The tongue, the nervous symptoms, the blood, and the bone-marrow are all typical of pernicious anæmia. In Meulengracht's cases complete achylia was demonstrated in every case on which a test-meal was done; in one of his cases the test-meal was normal six years before the anæmia developed, but achlorhydria was present when the anæmia was detected. Becker (1930), Little, and A. F. Hurst (personal communication) have since described cases in which there was a normal secretion of hydrochloric acid. Thus achlorhydria is not an integral part of the disease, and it may be the result of the intestinal stricture. The anæmia responds to liver treatment with a reticulocyte crisis and prompt regeneration of the blood.[7,37,43,63] Seyderhelm's patient recovered without other treatment when the stricture was resected. Little's patient relapsed on omitting liver after the normal anatomy of the intestine had been restored, but diarrhœa was still present, and the normal function of the intestine had obviously not been regained.

The coexistence of such rare conditions as pernicious anæmia and intestinal stenosis points to an ætiological connexion, which was proved when Seyderhelm produced pernicious anæmia in two out of ten dogs by ligating the small intestine. He showed that the onset of anæmia was more closely related to the growth of an abnormal intestinal flora than to the degree of narrowing of the gut. He suggested that pernicious anæmia was due to the absorption of bacterial poisons from the intestine, that their growth was favoured by achylia, and that their absorption was due to abnormal permeability of the intestinal wall. There is no evidence that toxins are absorbed or circulate in pernicious anæmia, or that toxins can produce pernicious anæmia. It is simpler to assume that if the intestinal bacteria play a part, it is either the destruction of the hæmatinic principles of the food by their metabolic activities, or the impairment of digestion and assimilation by their local effects on the mucosa of the stomach and intestine. In conclusion, I should like to point out that the anæmia of intestinal stenosis is not always, and perhaps not most frequently, of the megalocytic type, for a hypochromic anæmia may develop in simple stenosis of the intestine, where there is no hæmorrhage or gross infection and toxæmia.

Miss A had operations for tuberculous glands in the neck and the mesentery at the age of 14. In adolescence she suffered from bilious attacks for which her gall-bladder and appendix were removed without benefit. At the age of 20 she was found to have chronic duodenal stasis, ileal stasis, and calcified abdominal lymph glands; the test-meal was normal, and the hæmoglobin 85 per cent. At the age of 22 she had definite obstruction of the terminal loop of the ileum, which was dilated, half full of gas, and lifted out of the pelvis: there was no occult bleeding; the blood count was: red cells, 3,880,000 per c.mm.; white cells, 8000; Hb., 64 per cent.; colour-index, 0·83. She was treated by Dr. Hurst with a low-residue diet, belladonna, liquid paraffin, and grs. 75 of iron and ammonium citrate a day, and two years later her symptoms were much better, the obstruction had diminished, and the hæmoglobin was 87 per cent.

A man, aged about 40, was readmitted to Guy's Hospital six months after an operation for strangulated hernia. He now had a stricture of the ileum and a moderate hypochromic anæmia. He succumbed to the operation for the relief of the stricture, and I found normoblastic hyperplasia of the bone-marrow in the centre of the humerus.

INTESTINAL PARASITES.

Much of the literature of the association of pernicious anæmia with intestinal parasites is uncritical, and the subject is worthy of careful review by one interested in hæmatology and parasitology. Many intestinal parasites have been reported in association with pernicious anæmia, but the only one which occurs with any frequency is *Dibothriocephalus latus*. Even so, pernicious anæmia from *D. latus* infestation is rare, and it has been calculated that in Finland, where many are infested with this worm, only from 0·1 to 0·5 per cent. of those infested develop anæmia. It also appears that the victims of *D. latus* anæmia are often predisposed to pernicious anæmia by heredity or by achlorhydria. Achlorhydria occurs in over 80 per cent. of cases, but it is sometimes the result of the disease, and free acid may return when the worm is expelled.[45,69] *D. latus* anæmia is of great interest, inasmuch as it may be repaired either by expulsion of the worm or by treatment with liver. Expulsion brings about a complete cure, while liver merely repairs the anæmia, which will relapse if liver is discontinued, and the parasite allowed to remain.[7] Many attempts have been made to explain *D. latus* anæmia by the liberation of hæmolysins from the parasite, but opinion is now changing to the view that it depends on the destruction of the hæmatinic principles of the food by the parasite, or diminished intestinal absorption.

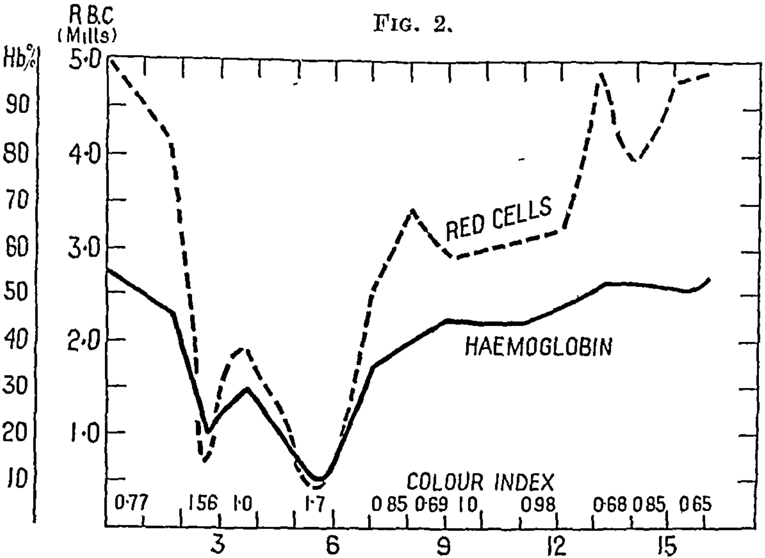
GASTRO-INTESTINAL ULCERATION.

Many instances have been reported of pernicious anæmia in association with cancer of the stomach,[59] dysentery, and tuberculous ulceration of the bowel.[32] Complex factors are at work in these cases, such as achylia, intestinal dyspepsia, hæmorrhage, toxæmia, and defective diet, but the anæmia may respond well, and with the typical reticulocyte crisis, to treatment with liver.

Fatty Diarrhœa.

Donald Hunter has described the disturbances in the metabolism of calcium and phosphorus which occur in fatty diarrhœa, and the consequent changes in the skeleton. The effects of fatty diarrhœa on the erythron are equally striking. If fatty diarrhœa persists for more than a few months, anæmia almost always develops. It tends to pass through the following stages: (1) hypochromic anæmia with normoblastic marrow; (2) megalocytic anæmia with megaloblastic marrow; (3) aplastic anæmia. At any of these stages recovery or death may occur, according to the progress of the primary malady. Characteristic changes in the white cells are lacking, and there is no shift to the right as in Addison's anæmia. Aplastic traits appear early, and though van den Bergh's reaction may be positive in the megalocytic stage, it is not so constant nor so intense as in Addison's anæmia. Liver produces a reticulocyte crisis and repair of the anæmia in the megalocytic phase, but is apparently without action in the hypochromic and aplastic phases.

FIG. 2.



Course of anæmia of cœliac disease.

It is natural to attribute the anæmia of fatty diarrhœa to the disturbance of intestinal digestion. On the other hand, glossitis and achlorhydria are frequent in all forms of fatty diarrhœa, and in sprue Castle has shown that the intrinsic factor may be absent even though hydrochloric acid is secreted freely by the stomach. Defective gastric digestion may therefore play a part in the anæmia of fatty diarrhœa. There is little doubt that the achlorhydria is often the result of the fatty diarrhœa, for several cases have been reported in which gastric secretion was normal at the onset, depressed at the height of the illness, and restored on recovery.

TABLE I.—*Blood Changes in 39 Cases of Cœliac Disease (Fanconi).*

Hæmoglobin per cent.	No. of cases.	Red cells in millions.	No. of cases	Colour-index.	No. of cases.	White cells in thousands	No. of cases.
70–60	8	6–5	9	1·5	1	20–15	1
60–50	11	5–4	11	1·5 –1·25	2	15–10	9
50–40	7	4–3	15	1·25–1 0	2	10–7·5	11

CŒLIAC DISEASE.

The blood changes in cœliac disease are evident from Table I., which summarises Fanconi's observations. In his 39 cases the hæmoglobin was below 60 per cent. in 31, and below 30 per cent. in 6. The various phases of hypochromic, megalocytic, and aplastic anæmia were clearly evident, and Fanconi observes that these are not separate entities but merely different degrees of anæmia, through which the same child may pass in the course of the illness (Fig. 2). In three of the 39 cases the blood picture was identical with that of Addison's anæmia—*profound anæmia of the megalocytic type*, leucopenia and thrombopenia, hyperbilirubinæmia, and excessive output of bilirubin derivatives in the fæces. They differed from Addison's anæmia in that the secretion of free hydrochloric acid by the stomach might be normal and complete cure might be obtained. In fatal cases aplasia of the marrow was found, but there was at times considerable hæmosiderosis.

SPRUE.

Sprue is disease of tropical and subtropical countries more often occurring in th newcomer an the better class of people. It is characterised b sore mouth and tongue, anæmia, fatty diarrhœa loss of weight, and a tendency to remissions an exacerbations. Its ætiology is unknown. It is distinguished from pernicious anæmia not only by th characteristic diarrhœa, but by the low calcium content of the serum, the dilated colon, and the frequen presence of free HCl in the gastric juice. Subacut combined degeneration of the cord is a rarity in spru and I know of no case in which it has occurred alon with a normal gastric secretion. Nevertheless, ther are many cases which seem to share the features sprue and pernicious anæmia, and which "in th tropics would be called sprue, while out of the tropic they would be called pernicious anæmia; the diagnosis is largely a matter of geography."[73] Such case have been described by MacLester.

In a consecutive series of 26 cases Fairley an co-workers found hyperchlorhydria in 4, norm secretion in 7, hypochlorhydria in 8, and achlorhydria in 7; in the achlorhydric patients the chlorid secretion was such as to suggest that some acid wa secreted but was neutralised. Castle and co-worke found no "intrinsic factor" in sprue with megalocytic anæmia in spite of free secretion of hydrochloric acid. The number of such experiments small, and it would be premature to conclude tha the anæmia of sprue is always purely gastrogenous.

A woman described by Wood had typical spru diarrhœa, but in addition achylia and subacut combined degeneration of the cord.

A patient of mine was in the West Indies for four month in 1914, at which time she was 23 years old, then returne to England, and worked as a nurse. She suffered continually from glossitis and anæmia. In 1921 she went t China, and 18 months after her arrival developed typica sprue. She came home in 1928 and made a good recover on diet, liver treatment, and transfusions. In 1929 she wen to Jerusalem, and there nearly died from pernicious anæmia n I saw her in 1931 the anæmia had recovered on ment with desiccated stomach, but she had well-marked ate combined degeneration of the spastic type.

he anæmia of sprue is usually not so severe as icious anæmia, and Fairley points out that while 80 per cent. of cases of pernicious anæmia have than two million red cells at the first examina-, patients with sprue come with a red count ween two and four million, and less than 20 per are below this level. Exact knowledge of the atology of sprue dates from the pioneer observa-s of Hampson and Shackle, who published Price-es curves from a number of cases in 1924, which ed a megalocytic anæmia. It is now known the anæmia of sprue tends to pass through three es.

An initial stage of slight anæmia, the colour-index g low, and the changes in the bone-marrow quite ate.

An intermediary stage characterised by hyperplasia he bone-marrow with abundance of megaloblasts and alocytic anæmia.

A final stage of hypoplasia or aplasia of the bone-row with the blood picture of aplastic anæmia.

here are less polychromasia and punctate baso-lia than in pernicious anæmia, and nucleated red s are infrequent, but true megaloblasts may ur. Hyperbilirubinæmia is uncommon, and there no constant changes in the white cells. In the galocytic phase the anæmia responds to liver with eticulocyte crisis and an increase in the red cells l hæmoglobin, but liver has no effect in the hypo-omic and aplastic phases.

In Fairley's 67 cases the colour-index was above ity in 61 per cent. It was never really low, for no e was below 0·7. During the first few weeks of ess the colour-index was found under unity in out of seven cases, but shortly afterwards high ices were established and were maintained through-t the course of the disease. In 10 out of 11 cases, all but one of whom the colour-index exceeded ity, the Price-Jones curve was shifted to the right. e bilirubin content of the blood was rarely reased. The bone-marrow, examined at death in ght patients, showed megaloblastic degeneration three and aplasia in the other five. Fine granular gment was constantly found in the liver and other sues, but not all of it was iron, and hæmosiderosis as less striking than in pernicious anæmia.

Krjukoff's study of sprue in middle Asia gave sults in correspondence with those of Fairley in India. Krjukoff (1927) noted that megalocytosis gave place to hypochromia during the stage of recovery. He examined the bone-marrow at biopsy, and found hyperplasia and megaloblastic degeneration in every case. This was most marked when the anæmia was of moderate severity, and at times it rivalled anything found in pernicious anæmia. Megaloblasts were present in early cases also, but the dedifferentiation of the bone-marrow was not so advanced and the megaloblasts were still capable of maturing into normoblasts and microcytes.

TABLE II.—*Blood Count in 67 Cases of Sprue.*

Hæmo-globin per cent.	No. of cases.	Red cells in millions.	No. of cases.	Colour-index.	No. of cases.	White cells in thousands	No. of cases.
>100	1	6–5	6	1·6	2	>15	3
100–80	17	5–4	13	1·6–1·4	2	15–10	8

40–20	6	2–1	11	1·0–0·8	20	5·0–2·5	22
20<	1	1–	1	0·8–0·6	6	2·5<	—

In Baumgartner's series of 36 cases, mainly patients from China under treatment in U.S.A., 16 had a megalocytic anæmia, 12 a hypochromic anæmia, and 8 no anæmia. In those with a megalocytic anæmia the mean diameter of the red cells was 8·2 microns, the range being from 5·9 to 10·7 microns, figures strictly comparable with those of pernicious anæmia. In one of the cases with hypochromic anæmia and very low hæmoglobin the cells were smaller than normal (6·7 microns), while in another they were larger (8·0).

CHYLOUS DIARRHŒA.

In recent years much interest has been taken in a nutritional disturbance in adults in temperate climates, which resembles cœliac disease and sprue, and which is often called non-tropical sprue. The symptoms are fatty diarrhœa, an extreme degree of emaciation, severe anæmia, low blood calcium with its associated sensory and motor phenomena, and a lowered rate of metabolism, all these latter symptoms apparently being due to malabsorption of food and minerals. Changes in the spinal cord are unusual, but Munford's patient developed signs of subacute combined degeneration in spite of normal secretion of hydrochloric acid in the gastric juice. The stools are copious, greasy, and pale, containing an excess of fatty matters, chiefly as split fats; *Monilia psilosis* is not found. Rontgen examination reveals a distended colon and decrease in the density of the bones. In cases coming to operation or autopsy obstruction of the lacteals by tuberculous or other disease has been found,[52] and this obstruction to the absorption of fat may well be the root cause of the disease. In other cases, however, no post-mortem changes have been detected.

The hæmatology of chylous diarrhœa is identical with that of sprue, as may be seen from Table III., which is compiled from 26 cases taken from the literature, 4 under the care of Dr. A. F. Hurst, and 2 of my own. The anæmia may be hypochromic, megalocytic, or aplastic. Van den Bergh's reaction was negative in all of 7 cases in which it was performed, but Hegler found hæmatinæmia, as in Addison's anæmia. Test-meals were done on 25 patients, and the result was normal in 11, hypochlorhydria in 4, and achlorhydria in 10. The tongue was normal in 6, inflamed in 17. Umber, in a reference which I have been unable to study, describes the post-mortem findings in the bone-marrow as those of aplastic pernicious anæmia. The following cases are of special interest:—

One of my cases, a man of 62, was first diagnosed as Addison's anæmia on the basis of glossitis, achlorhydria, and a blood count of red cells, 2,500,000 per c.mm.; white cells, 3400; hæmoglobin, 55 per cent.; colour-index, 1·1, with megalocytosis. Further investigation showed that van den Bergh's reaction was negative, there were translucent areas in the bones, and there were up to six fatty motions a day. The test-meal was repeated after lavage, when the secretion of HCl proved to be normal. On treatment with HCl and liver extract the diarrhœa decreased to two motions a day, the hæmoglobin rose to 64 per cent., and 9½ lb. in weight was gained. He died two and a half years later after developing so much scoliosis that "his spine seemed to have shrunken."

Mrs. B, aged 48, who has a strong family history of tuberculosis, has been under my observation for 18 months with fatty diarrhœa, glossitis, hypochlorhydria, and cramps in the legs. Her blood count when first seen was: red cells. 3.100,000 per c.mm.; white cells. 5200; hæmoglobin, 54 per cent.; colour-index. 0·85; negative van den Bergh reaction. She had thorough treatment with liver, desiccated stomach, iron, and hydrochloric acid, but made no improvement till she was placed on a low-fat diet with calcium and vitamin D.

Hegler's patient in the spring of 1922 had a blood count of red cells, 4,630,000 per c.mm.; white cells, 6000 hæmoglobin, 58 per cent.; colour-index, 0·6; van den Bergh's reaction was negative, and there was hyperchlorhydria. In May, 1923, the blood count was red cells, 1,100,000 per c.mm.; white cells, 5000; hæmoglobin, 30 per cent.; colour-index, 1·4; the test-meal now showed anacidity, and there was hæmatinæmia. In the summer of 1928 she was much better, and the blood count was: red cells, 4,500,000 per c.mm.; white cells, 6500; hæmoglobin, 70 per cent.; colour-index, 0·8.

In Holst's patient there was glossitis with normal gastric acidity. The blood was very carefully examined by Gram: red cells, 1,320,000 per c.mm.; white cells, 4000; hæmoglobin, 39 per cent.; colour-index, 1·5; megaloblasts were present; the Price-Jones curve was typical of an Addisonian anæmia; the mean diameter of the red cells 8·5 m., the mean volume 136 cubic microns, the icterus index was 4.

TABLE III.—*Blood Changes in 32 Cases of Chylous Diarrhœa.*

Hæmoglobin per cent.	No. of cases.	Red cells in millions.	No. of cases.	Colour-index.	No. of cases.	White cells in thousands	No. of cases.
99–80	6	5–4	12	>1·4	3	>15	1
79–60	10	4–3	8	1·39–1·2	5	15–10	3
59–40	12	3–2	6	1·19–1·0	9	10–7·5	6
39–20	3	2–1	5	0·99–0·8	9	7·5–5·0	14
19<	1	1–	1	0·79–0·6	6	5·0<	8

PANCREATOGENOUS DIARRHŒA.

Walko comments on the frequency of anæmia in chronic pancreatitis, and describes a case of pancreatitis with typical pernicious anæmia. Holler and Kudelka found mild anæmia and increased diameter of the red cells very constantly not only in chronic pancreatitis but also in jaundice and in cirrhosis of the liver without jaundice. It is probable that a number of different factors are at work in these cases, such as achlorhydria, fatty diarrhœa, changes in the portal blood pressure, and in the chemical composition of the plasma, so that no special significance can be attached to them. For example, Thaysen reports four cases of pancreatic disease, two of whom had mild anæmia with high colour-index, but all four had achlorhydria or hypochlorhydria.

GASTRO-COLIC FISTULA.

Gastro-colic and jejuno-colic fistulæ are usually the result of gastric carcinoma or of gastro-jejunal ulcer. The most constant symptom is fatty diarrhœa, the other food elements being much better digested than might be expected. Fairley and Kilner have reported three cases with glossitis and megalocytic anæmia, which bore a close resemblance to sprue. Two of them, both with normal gastric acidity, were treated with a high protein diet and liver with great improvement in the anæmia. Poynton and Macgregor have reported a case of gastro-colic fistula with anasarca and hypochromic anæmia; there was no active ulceration or bleeding. One cannot but be impressed by the frequency of glossitis and anæmia in fatty diarrhœa of such different origins, and by the similarity of the effects produced on the erythron and the skeleton. The natural conclusion is that they are the effects of diminished gastro-intestinal absorption of the hæmatinic principles and of the inorganic elements of the bones.

Pellagra.

The pathology of pellagra is still obscure. The primary lesions are confined to epithelial surfaces without extension to deeper tissues or organs. The cutaneous manifestations are well known, but it is important to note that "lesions of the mouth, tongue, and œsophagus are the most constant and consistent lesions of pellagra."[15] I have always been impressed by this likeness to the Plummer-Vinson syndrome, and by the fact that pellagra affects females twice as often as males. The stomach and small intestine show no consistent anatomical changes, but a colitis of variable intensity is present in every case. Peripheral neuritis and psychoses may develop, but there are no tract degenerations of the spinal cord like the subacute combined degeneration of Addison's anæmia. Achlorhydria is present in 85 per cent. of cases, hypochlorhydria in 9 per cent., and normal gastric secretion in 6 per cent. diarrhœa is present in 60 per cent.[65]

Anæmia is not a striking feature in pellagra, which leads to death from other causes before the erythro is much affected, but there is nearly always some diminution in the cells of the blood and the protein of the plasma. These are secondary effects of th disease, which represent impaired digestion a absorption of protein, and are dependent upon th injury to the alimentary tract. In 41 cases Krjukof (1931) found the hæmoglobin below 70 per cent in 20, and below 50 per cent. in only 4. The anæmi was hypochromic in 28, orthochromic in 8, an hyperchromic in 5. The serum was very pale even i patients with megalocytic anæmia. The marro reaction was sometimes normoblastic, sometime megaloblastic, sometimes aplastic, but usually mixed reaction was present, and there was no clos agreement between the blood picture and the marro reaction. It would appear that the nutritiona defect in pellagra is too extensive to allow such pu reactions as are found in simple and perniciou achlorhydric anæmia, and too intense to allow th sequence of reactions of normoblastosis, megalo blastosis, and aplasia, which take place in fatt diarrhœa. The usual findings in pellagra are a hypo chromic anæmia and a normoblastic marrow wit traces of megaloblastosis and aplasia.

Disease of the Thyroid.

The thyroid is the only endocrine gland diseas of which is attended by anæmia. The thyroid wa originally in communication with the alimentar canal, and the anæmia of hypothyroidism is ver similar to the anæmias of nutritional and alimentar disease. As we might expect from animal exper ments, which show that thyroxin stimulates bloo formation,[54] hyperthyroidism per se does not gi rise to anæmia.[35] But women who develop hyper thyroidism are often of the chronic abdominal invali type, and many of them have achlorhydria. Thi probably explains the severe anæmias which ar occasionally met with in women with hyperthy roidism.[21 23 51] Meulengracht observed perniciou anæmia 8 times in 151 women with hyperthyroidism, it developed relatively early in life, from 7 to 28 year after the onset of hyperthyroidism, and was o moderate severity.

In experimental animals thyroidectomy causes hypochromic anæmia with moderate hyperplasia o the bone-marrow.[17 54] I have found little informa tion about the bone-marrow in myxœdema, but ther is apparently a mixture of hyperplasia and aplasia i varying degrees. Anæmia is present in some hal of the cases but is rarely profound. The hæmoglobi is reduced to about the same extent as the red cell or a little more, so that the colour-index is usuall a little below unity. There are no marked chang in the size and shape of the red cells. Achlorhydri occurs in a rather high proportion of hypothyroi patients—4 out of 16 of Stone's cases and 3 out of 1 of mine. It is often permanent, and persists afte nt of the thyroid deficiency, but Boenheim the gastric acidity normal after thyroid treat- n two patients, who had had anacidity in the meal before. The clinical resemblance to ous anæmia may be great. Two of Stone's s had been treated for pernicious anæmia success; their metabolism was low, and næmia improved on thyroid treatment. In lema there is no increase in the amount of n in the blood, and the size of the red cells is reased.

ight be expected from their age-incidence and sociation with achlorhydria, pernicious anæmia yxœdema may coexist in the same patient. ive cases reported by Means, in three of whom nicious anæmia preceded the myxœdema, in e myxœdema developed first, and in the fifth was no evidence which came first. Each disease ded to its own treatment, and their association ed to be fortuitous. We need more informa- bout the anæmia of thyroid deficiency, more lly as regards the behaviour of the bone- w, the permanence of the achlorhydria, and the ity of the response to thyroid treatment. In perience thyroid is of no value in any other a. In the Plummer-Vinson sydrome, for which been specially advised, I have never been able et any effect. On the other hand, the anæmia othyroidism does not respond to iron, arsenic, sfusions, and probably not to liver.

Conclusion.

n well aware that I have set myself and those ead this lecture an arduous task in surveying ormous literature, and a wealth of clinical and mental material. Much has of necessity been d. I have avoided discussion of subacute ned degeneration and allied nervous diseases, h they are susceptible of the same explanations disturbances of the erythron.[68] Apart from othing has been deliberately overlooked. The ce I have presented shows that anæmia due turbance of erythropoiesis occurs in a variety itional and digestive disorders. It is possible plain each and all of these anæmias by the tion of the organism in the materials necessary ood formation. Some of these materials have ly been isolated—iron, copper, thyroxin, vita- B, vitamin C—and others, such as the active ple of liver, cannot long elude analysis. The ation may be the result of imperfect diet, or of red digestion or assimilation. The anæmia is o diminished blood formation, and it may be cytic, megalocytic, or aplastic in type, accord- o the stage at which erythropoiesis is arrested. accept this explanation, we must revise many r ideas about digestion, both in the stomach in the intestine, but in so doing we may gain light on digestive disorders. We must also e that such infection of the mouth and gastro- tinal tract as may be present in these diseases ually secondary to the metabolic or digestive t, and plays little or no part in the initiation e anæmia, but it must be confessed that the rial and hæmolytic theories of these diseases ill repaid the laborious investigations they have ed. The field has been surveyed only, and problems await solution. Time may play with our theories, but the conception of a p of nutritional and gastro-intestinal diseases, y related in signs, symptoms, and hæmatology, ely to have a permanent place in pathology, ine, and therapeutics.

THE TREATMENT OF DIABETIC URÆMIA WITH HYPERTONIC GLUCOSE SOLUTIONS.

BY H. W. FULLERTON, M.B. ABERD.,
HOUSE PHYSICIAN ABERDEEN ROYAL INFIRMARY;
A. LYALL, M.D. ABERD., M.R.C.P. LOND.,
LECTURER IN CLINICAL CHEMISTRY IN THE UNIVERSITY OF ABERDEEN:
AND
L. S. P. DAVIDSON, B.A. CAMB., M.D., F.R.C.P. EDIN.,
REGIUS PROFESSOR OF MEDICINE IN THE UNIVERSITY.

THE case reported below was admitted to the Aberdeen Royal Infirmary in diabetic coma, and passed into uræmia and anuria, eventually making a complete recovery. The extreme rarity of recovery under these conditions appears to warrant the publication of an individual case.

Case Record.

Miss A., aged 27, was admitted to hospital on Oct. 26th, 1931, unconscious, with marked air hunger, exhaling acetone strongly, and with her urine loaded with sugar and acetone. The case was diagnosed as diabetic coma.

Previous history.—About May, 1929, the patient began to get easily tired, to be a little thirsty, and to notice that she was slightly thinner. Her family doctor found sugar in her urine, and accordingly sent her for investigation to the Royal Infirmary. Her fasting blood-sugar was 218 mg. per 100 c.cm. She was placed on a diet to which she strictly adhered, and in consequence enjoyed good health. At subsequent examinations the fasting blood-sugar was always in the neighbourhood of normal. In January, 1931, she developed an ischio-rectal abscess on the right side, which burst. Apart from local discomfort this infection produced no general manifestations.

Present illness.—About a week before admission the patient developed another ischio-rectal abscess on the same side. This was treated with hot fomentations. The day before admission the patient began to feel off colour and seedy, and next morning gradually passed into coma. On admission she was definitely, but not deeply, unconscious, since resistance to passive movement was present. Respiration was deep and sighing. There was a strong smell of acetone in her breath. The skin was cold and clammy. The tension of the eyeballs was greatly reduced. The pupils were moderately dilated, and reacted sluggishly to light. The blood pressure was 122/70, the pulse-rate 96, and the temperature 97·2° F.

General examination.—Nutrition good. Respiratory, alimentary, and cardiovascular systems satisfactory. Nervous system normal. Plantar reflexes were flexor. A large ischio-rectal abscess was found in the right side, and was immediately opened. Black material, which was a mixture of pus and fæces, was evacuated. Small blue areas on the pads of several toes, suggestive of early gangrene, were present.

Laboratory data on admission (11.25 a.m., Oct. 26th).—Urine, catheter specimen, amount 8 oz., clear amber colour, acid reaction, specific gravity 1032. Sugar +++, 6·2 per cent. Acetone and diacetic acid +++. Albumin ++. Chlorides diminished. Microscopic examination of deposit: *many granular casts, scanty* hyaline casts, and epithelial cells. No erythrocytes or pus cells. Blood-sugar, 451 mg.; urea, 33 mg.; and chlorides, 613 mg. per 100 c.cm.

TREATMENT.

The patient was covered with warm blankets and surrounded with hot-water bottles. At 12 noon 50 units of insulin were injected subcutaneously. Within half an hour she partially regained consciousness, and 30 g. of glucose were given orally.

At 1 P.M. 40 units of insulin were given, and at 2 P.M. and 3 P.M. 30 g. of glucose. At 4 P.M. the blood-sugar was 486 mg. per cent., and the urine still contained considerable quantities of sugar and ketone bodies. Accordingly, 60 units of insulin were given, together with 30 g. of glucose. At 4.30 P.M. the patient sufficiently recovered consciousness to be able to answer questions. At 5 o'clock *30 g. of glucose were again given*, with continued improvement in every way. The patient, at this stage, was taking plenty of fluid by mouth. At 8 P.M. another 40 units of insulin were given. At 10 P.M. the patient was sleeping comfortably, respiration still sighing, acetone in breath and diacetic acid in urine present, but much less marked.

At 12 P.M. a catheter was passed, and only one ounce of urine was found in the bladder. Sugar and acetone were present, but much less in amount, while only a trace of diacetic acid was found. Blood was withdrawn, and the result of the estimation done next morning showed that the blood-sugar was 382 mg. per cent. The blood-urea had risen to 55 mg. per cent. and the chlorides remained approximately stationary at 627 mg. per cent. She was given 30 g. of gluco

id 20 units of insulin. During the first 12 hours e patient received 190 units of insulin and 150 g. sugar. At 5 A.M. the bladder again contained ly an ounce of urine. in which a trace of sugar and etone was found. and no diacetic acid was present. ir-hunger was absent, so further insulin treatment as temporarily discontinued. At is time vomiting was first noticed. ark bilious material was brought p, the act having no relation to od.

For the following four days the atient was practically anuric. nce approximately two ounces of rine was all that could be obtained ach 24 hours by repeated catheterisation.

During this period she lay in an tremely lethargic condition, but was ble to understand simple questions. he temperature swung in an irregular anner between normal and 101° F. he blood pressure varied from 102 o 122 on different occasions. and the ulse-rate from 100 to 146. Although lenty of fluid was given by the mouth, he severe and continuous vomiting as uickly removed it, so that fluid was robably not absorbed by this route. ccordingly, approximately two pints f normal saline, containing 5 per cent. lucose, were given intravenously uring each 24 hours, and about 30 nits of insulin were injected subcutaneusly three times a day. Numerous lood-sugar estimations during this period showed that the vel varied from 120 to 300 mg. per cent., while the bloodrea steadily rose until on the fifth day after admission it eached 224 mg. per cent. The plasma chlorides were still ractically stationary, at approximately 600 mg. per cent. he small amount of urine obtained boiled almost solid ith albumin. and microscopic examination revealed large umbers of granular casts and red cells, signifying an acute oxic nephritis.

A résumé of the laboratory and clinical data is given in the accompanying table and chart.

THE USE OF HYPERTONIC INTRAVENOUS GLUCOSE.

A consideration of these facts led us to the conclusion that the condition of the patient had altered from diabetic coma to what might be described as diabetic uræmia. The position appeared to be critical. since in our experience patients with diabetic coma who develop a definite anuria, and in whom the blood-urea reaches 150 mg. per cent. or over, invariably die. The facts supporting this contention are appearing in a separate paper at an early date Simple remedies, such as hot fomentations and cupping the loins, had failed. Irritant diuretics appeared to be contra-indicated, as judged by the presence of blood and casts in the urine. As a last desperate resort it was decided to try to restart urinary secretion by raising the blood-sugar level to a high degree with hypertonic intravenous glucose. The matter is discussed in detail at the end of this paper.

Accordingly. at 5 P.M., and again at 10 P.M., on Oct. 30th. one pint of a 25 per cent. glucose solution in normal saline was given intravenously. The solution was introduced very slowly. about 40 minutes being taken for the injection. At 12.30 A.M. 8 oz. of urine were passed: this contained some sugar but no diacetic acid. During the rest of that day 20 oz. were passed. At 7.30 P.M. on Oct. 31st another pint of 25 per cent. glucose in normal saline was given intravenously. On the following two days, 3½ oz. and 52 oz. of urine were passed, and subsequently normal urinary secretion occurred. The blood-urea, which on the sixth day after admission had reached a maximum of 230 mg. per cent., steadily fell and returned to normal figures in nine days. The plasma chlorides, which up to this date had been somewhat above normal. fell to a figure slightly below normal.

No attempt was made to reduce the blood-sugar level to normal, since a definite danger from coma still existed, in view of the sepsis from the unhealed ischio-rectal abscess. The occurrence of a right-sided pleurisy with effusion. which started on Nov. 4th. was an additional reason for this policy. Adequate glucose and insulin were given daily to control all signs of ketosis.

On Nov. 9th aspiration of the right chest showed that a cloudy fluid was present in the pleural cavity. Microscopic examination revealed numerous polymorphs. but bacteriologically the fluid was sterile. During the subsequent four weeks the temperature gradually ceased to swing and returned to normal, where it has remained for the past month. The fluid has disappeared from the pleural cavity. some dulness at the base remains. and a few fine crepitations can be heard at the end of inspiration.

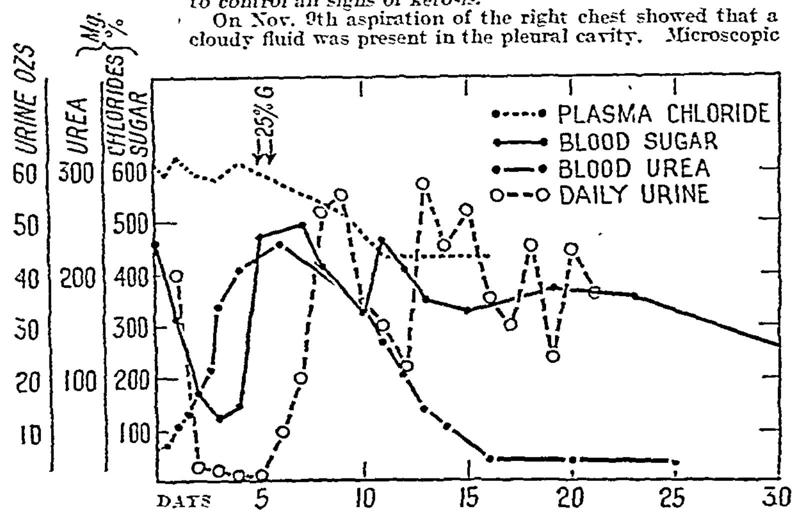

Chart showing effect of two injections of 25 per cent. glucose solution at points marked by arrows.

The urine is now normal in quantity, and the maximum concentration after the administration of 15 g. of urea is 2·3 per cent.; it is free of albumin, sugar, ketone bodies, casts. and cells. The ischiorectal abscess is healed. The diet has been gradually increased to 1800 calories. with 20 units of insulin twice daily. The patient's nutrition is excellent, and a complete recovery may now be said to have been achieved.

Discussion.

A number of observers have noted the occurrence of uræmia as a sequel of diabetic coma.

Joslin[1] emphasises a fact, already well recognised. that renal changes frequently occur in diabetic coma. though oliguria, and especially anuria, are uncommon. Ambard and Merklen[2] published a case in which the blood-urea increased to 180 mg. per cent., while the plasma carbon dioxide. after having been low, returned to normal and the patient died with nephritis. Merklen, Wolf, and Bicart[3] described a case somewhat analogous to our own, in a young woman in whom hyperglycosuria and acidosis were overcome by insulin treatment. but the patient developed an acute and fatal nephritis. with oliguria, albuminuria. and uræmia. John[4] observed a condition very like the present case in a young man in whom the blood-urea increased to over 200 mg. per cent., and remained at this level for five days. with retention of urine. Renal function was re-established by intravenous injection of 500 c.cm. of 1·4 per cent. saline and 1 per cent. sodium carbonate. and recovery took place. Unfortunately no information with regard to the volume of urine secreted or the blood chloride is available.

Recovery from diabetic coma, however, is rare when anuria supervenes, and in our experience the condition is nearly always fatal. Apart from anuria itself there may be evidence of nitrogen retention of almost any degree in the blood. If the increase in blood-urea be taken as an index of the failure of renal function, it would appear that the chances of recovery are low when this value is increased above 100 mg. per cent. In our own series of cases [5] we found that only one death occurred amongst 13 patients with diabetic coma where the blood-urea did not exceed 100 mg. per cent., but that four out of a total of six patients died where the blood-urea was above that figure. Combining the 31 cases collected from the literature by Labbé and Boulin [6] with our own figures, we find 56 cases of diabetic coma with elevation of the blood-urea. In 34 of these, where the value did not exceed 100 mg. per cent., there were six deaths, while 14 deaths occurred amongst 22 cases where the blood-urea value was over 100 mg. per cent. But the present case, along with that of John,[4] is evidence that recovery may still take place even when much higher blood-urea values are present, provided the urinary secretion can be re-established.

There is no doubt that renal function is to some extent disturbed in nearly all cases of diabetic coma, as evidenced by the presence of albumin, casts, and sometimes blood in the urine. Several factors are concerned in this type of renal failure, and a study of the literature would suggest that their importance varies in individual cases. These factors can, however, be classified as follows:—

(*a*) Circulatory disturbance in the kidney accompanying fall of blood pressure and cardiac failure.

(*b*) Dehydration of the blood-plasma due to lack of intake of fluid. previous polyuria, and often to vomiting (Bulger and Peters [7]).

(*c*) Increase [illegible] ogen metabolism (Lyall [8]).

(*d*) Actual [illegible] in the renal parenchyma, due to the e[illegible] of ketonic acids and salts and other metabolites in the early stages of the coma (Snapper [9]).

The increase in blood-urea is probably not wholly an index of the failure of renal function, since concentration of the chemical constituents of the plasma, including urea, is brought about by dehydration, as has been shown by Bulger and Peters.[7] Increased endogenous nitrogen metabolism also tends to cause an increase in the blood-urea, but in the later stages, when oliguria or anuria has supervened, the great increase in the blood-urea is almost certainly due to direct retention.

Blum, Grabar, and van Caulaert [10] have adduced evidence for the interesting suggestion that the azotæmia in diabetic coma is due not to a partial anuria, to renal changes or to the acidosis itself, but to the loss of salt from the blood and tissues. If this hypothesis were substantiated it would bring the azotæmia of this type into line with that which accompanies salt loss in conditions like upper intestinal obstruction, pyloric stenosis, and intense diarrhœa. These authors cited two cases of diabetic coma where the blood chlorine decreased to 284 mg. per cent., and the urea reached 480 mg. per cent. upon a chlorine-free régime. The blood-urea values rapidly returned to normal after administration of sodium chloride by mouth. But they failed to repeat these observations in other cases of diabetic coma, even in one of the same individuals in a later attack of coma. It should be remarked that both of the cases in which they originally observed the decrease in chlorides suffered from severe diarrhœa of 15 days' and 10 days' duration respectively—a condition in itself likely to cause hypochloræmia. In our own case the plasma chlorides remained high during the period of anuria, and did not commence to fall until the urinary flow restarted. In further observations of our own we have never found the plasma chloride low in diabetic coma, and in this we are supported by the careful researches of Bulger and Peters,[7] who in an investigation of the phenomena of dehydration in diabetic coma found the plasma chlorides to be either increased or normal. They usually observed that a marked increase occurred in the excretion of chloride during improvement, as also occurred in our own case. The kidney normally excretes chloride in abundance when the plasma chloride is above 520 mg. per cent. The fact that the urine of our patient contained only minimal traces of chloride, while the plasma chlorides were over 600 mg. per cent., is ample evidence of the inability of the kidney to excrete this substance.

Two problems are of particular interest in this case. (1) What is the cause of anuria in diabetic coma? (2) What factors influenced the renewal of urinary secretion? Information available at present makes it impossible to state categorically whether the anuria in diabetic coma is primarily the result of a nephritis caused by the excretion of irritating ketone bodies or whether the nephritis is secondary to dehydration, disturbances of osmotic equilibrium, and alteration in capillary circulation. The renal damage, and anuria which occurs in high intestinal obstruction in human beings and in experimental obstruction in dogs is undoubtedly in some way associated with salt loss. We can definitely say that this was not the cause of anuria in the present case, and we ar inclined towards the opinion that the anuria was th sequel of a parenchymal change in the kidney du to temporary toxic causes. The renewal of urinary secretion in this case followed the intravenous administration of hypertonic glucose.

A similar procedure has been found effective in children dehydrated by prolonged diarrhœa, as reported by Hoag and Marples,[11] who used 10 per cent glucose intravenously. Similarly, Comfort and Snell used 20 per cent. intravenous glucose to stimulat renal secretion in patients with anasarca secondar to cirrhosis of the liver. The mechanism causing th renewal of the urinary flow in the case reported b John does not appear to be the same as in the presen instance, since the solution given was only slightl hypertonic, and in our case several previous intra venous injections of normal saline with 5 per cen glucose had proved ineffective.

It is recognised that the kidney has a vital capacit for the secretion of certain substances when these a present in the blood stream above the threshold lev Sugar and chlorides were already present in co centration much above that level, and there was al a marked retention of urea. Raising the blood-sug level still higher by the intravenous injection hypertonic glucose does not appear to be a satisfacto explanation in itself for the subsequent diuresis. appears more probable that the renewed urina excretion was due to a disturbance of osmotic equi brium. Although clinically no evidence of œdem was recognised, experimental work on depancreatis dogs shows that tissue œdema may occur in t absence of gross clinical signs of its presence. Mig tion of fluid back into the capillary channels mig occur by a sudden disturbance of osmotic equilibriu such as would be caused by the introduction of fi times isotonic glucose solution. A gradual chang on the other hand, might not accomplish this, sin it would only result in equilibrium being re-establish at a new level. The result of a change in osmo pressure would be an increased blood volume, impro ment in the general circulation. better oxygenati of the blood, and increased blood flow through t kidney. These factors, in our opinion, may be t explanation of the renewed renal activity.

PECIFICITY OF THE "PROTEOSE" INTRADERMAL REACTIONS.

By John Freeman, M.D. Oxf.,

TRER IN BACTERIOLOGY AND DIRECTOR OF THE DEPARTMENT
CLINICAL BACTERIOLOGY, ST. MARY'S HOSPITAL, LONDON.

r. G. H. Oriel obtained a white precipitate from ie which he called "proteose"; he claimed that n this is isolated from an asthmatic patient's ie and injected into him intradermally "a reaction ults which is similar to that seen on the injection an antigen to which the allergic patient is sitised."[1]

his, if true, would be of the greatest importance: ady an immunotherapy has been based on it, l practitioners are sending cases of asthma, eczema, , to me, and without doubt to others also, with request "please treat with proteose." It does matter to pathology that the allergic diseases, amenable to suggestion, should be the happy ating ground of the experimental therapist; but abtful scientific theories should be tested, however congenial this work may be, or they may confuse ther research. At the end of November last I ve my reasons for believing this basic fact of the ecificity of the proteose to be wrong—or at least proven.[2] Since that date attempts have been made both sides at conversion, and I think that Oriel and s fellow-workers would no longer claim that the eged specific reaction was "similar to," let us say, e pollen reaction in a hay-fever patient. But he ill claims some specificity, as indeed he must if his eory is to stand on its feet and if his proteose therapy to be scientifically justified. I therefore made ore elaborate intradermal tests to confirm or remove y own doubts.

It will make things clearer if I explain at the eginning what I only learnt half-way through my ivestigations: proteose is not a chemical substance, ut a more or less fortuitous collection of substances roduced by the excretory activities of the kidneys. ith Oriel's latest technique, as well as with his arlier and less precise methods, you get "proteose" rom everyone's urine, but the iller the person the nore you tend to get of it. Proteose is always toxic, s might be expected; if injected into any man's kin, and if taken from any source—well or ill, llergic or non-allergic—you get in a few minutes a lightly raised wheal of varying size, and sometimes n erythematous flush round it, both wheal and flush fading in a few minutes more. The alleged specific reaction of proteose from an asthma patient on that patient's own skin is therefore not a question of positive and negative (as I first thought, and as it is with, say, grass pollen on the skin of hay-fever and non-hay-fever persons), but a question of slightly less or slightly more than one gets in the control cases —which are amongst themselves varying very considerably. Add to this the tendency to dermographia to which allergic cases are peculiarly prone, and it will be clear that for any critical opinion great caution must be taken in arranging the experiment.

THE HAY-FEVER "PROTEOSE."

In Fig. 1 the well-recognised reactions of pollen on the skins of hay-fever and of normal subjects (Columns I. and III.) are contrasted with the alleged hay-fever proteose reactions on neighbouring areas of skin on the same subjects (Columns II. and IV.). The pollen extract (poll.) was from my usual supply; the tests were made by placing drops of normal saline and of 10,000 unit pollen extract on neighbouring portions of skin, and then pricking through these drops with clean needles to the depth of perhaps a millimetre—i.e., till the person tested just experienced a faint prick; that is my usual technique for the diagnostic pollen reaction for hay-fever. The hay-fever proteose (H.F.P.). doubtless isolated from the urine of some hay-fever patient, was given me for testing by Oriel himself, together with his "control proteose" (C.P.)—i.e., a proteose isolated from a non-hay-fever subject. After a few tests I added normal saline as a second control. The tests of the proteose and its controls were made by intradermal injections of one-twentieth of a cubic centimetre of each of the fluids into neighbouring areas of skin—the method employed by Oriel and his fellow-workers. All these tests—the two pricks and the three intradermal injections—were made on three groups of persons: (1) the hay-fever subjects; (2) normal—i.e., non-allergic—subjects; and (3) allergic, but non-hay-fever subjects. All were taken as they came to hand and were not in any way selected, and all reactions have been traced off on glass and recorded without exception as they occurred.

It should be clearly understood that we cannot fairly compare the extent and the intensity of the reactions shown in Column I.—i.e., the pollen reactions—with the reactions in Columns II. and IV., because the prick through the drop of pollen extract into the skin can inject only a tiny fraction, say a fiftieth part, of the minim or so of fluid which was injected when testing the proteoses in Columns II. and IV. In spite of this the pollen reactions were as a rule more intense than the proteose reactions; the wheals were more raised, the flushes were more red, and both of them were longer lasting than the proteose reactions; after consideration no attempt has been made to indicate this in Fig. 1.

In all the reactions in Fig. 1 the central dot (where shown) indicates the point of entry of the needle; the unbroken ring shows the maximum extent of the wheal—usually in about 10 minutes; the broken ring shows the extent of the erythematous flush.[3] All the reactions were, as a rule, fading rapidly in 20 minutes, but, as has been said, the pollen reactions *tended to last somewhat longer*, besides being more intense.

I think we can say at a glance that Columns I. and III. in Fig. 1 show definite positive and negative

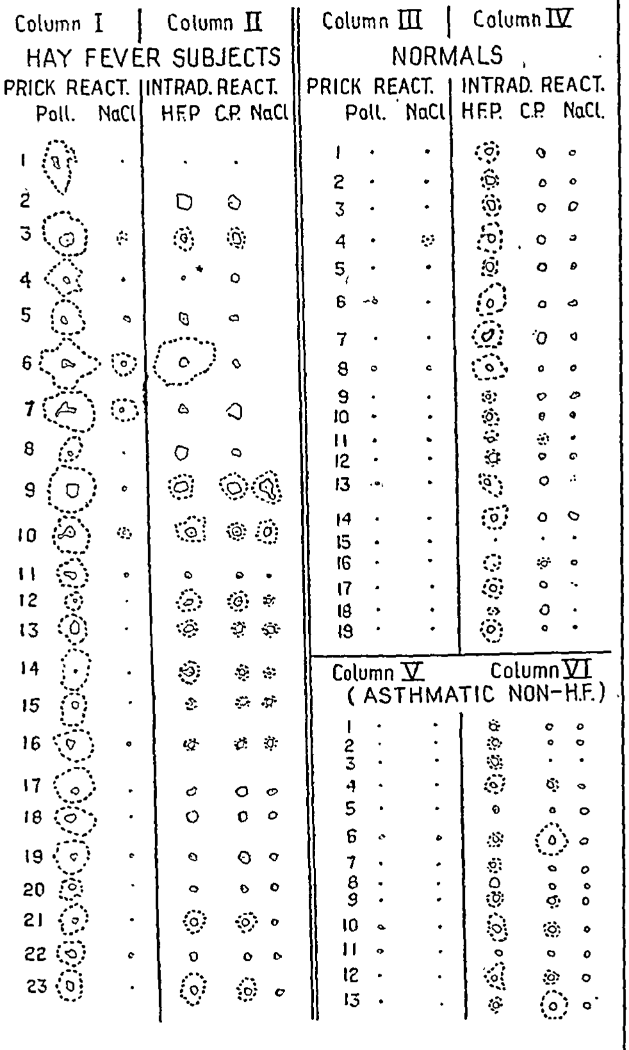
reactions respectively; for indeed the pollen reaction for hay-fever is about as reliable as the Wassermann reaction for syphilis. Columns II. and IV. should also show positive and negative reactions according to Oriel's story; they do not. One might perhaps have said that No. 6 in Column II. looks like a positive reaction, but it is discounted by the fact that the same subject shows in Column I. a "positive" reaction resulting from a prick through normal saline —i.e., this patient is dermographic. The proteose

FIG. 1.



reactions in Column IV. should all be negative according to Oriel's story (and according to mine, for that matter), but perversely enough many of them look like being positive [4] as shown in the figure, though their minor intensity. as compared with the true reactions from pollen in Column I., would probably render them dubious to anyone actually observing them.

THE ASTHMA-ECZEMA "PROTEOSE."

The intradermal reactions shown in Fig. 2 were all arranged after the controversial letters in *The Lancet* and *British Medical Journal*, and after I had seen at Guy's Hospital what very small differences were being taken to indicate a reaction, and the apparent lack of caution with which these possibly chance differences were being interpreted. In this intradermal technique (as in any other that I know of) it is possible to influence the result quite unconsciously to some slight extent, though I do not think that any clear-cut test like the pollen-hay-fever reaction could be obscured by this. The possibilities of error are these: (1) neighbouring areas of skin do not give quite the same reactions, the differences depending presumably on blood and nerve-supply [5]; (2) it is only normal human nature to see to it that the full one-twentieth of a cubic centimetre is injected of the fluid which according to theory ought to react, and to see to it that no excessive amount is injected of that which should not react; (3) apart from the mere amount of fluid we must consider the force and rapidity with which it is injected; (4) above all, the depth of injection into the skin makes a difference, for if given deep the reaction is lost or obscured, if very superficial the reaction is much more apparent.

It is possible, I think, to avoid all these sources of unconscious error if the injector does not know which fluid he is injecting or in what order he will be giving them. In Fig. 2 six different set of fluids had to be injected into the skin of each person tested; each fluid had its own particular syringe, and for each person the six syringes were shuffled till the injector did not know which was which till he looked afterwards at the inconspicuous identification marks. Thus a favourable or unfavourable site could not be chosen unconsciously.

Five proteoses were used, and to them was added normal saline solution to make the sixth fluid. O these five proteoses three were from pronouncedl allergic cases—two (O and J) were asthma-eczemas and one (P) was a bad case of asthma; the othe two proteoses were from normal persons—one (N from a rather nervous delicate young man, and th other (F) from a more robust but more elderl individual. These five proteoses were all extracte by my colleague, Dr. Roche Lynch, on publishe and unpublished instructions from Oriel, and aft a personal visit which Oriel kindly made to Roc Lynch's laboratory. The five proteoses were ma and used during the space of a few weeks only.

The control subjects were taken as they came hand and without discrimination between them. all three columns the reactions were traced off glass, and all recorded in the figure as they occurre The central dot again indicates the point of ent of the injecting needle; round this, however, the are here usually two unbroken rings. The inner o (marked with the thinner line) indicates the "pe d'orange" created by the injection itself, which w traced off on to glass immediately after the injectio The outer and thicker unbroken ring shows the great extent of the whealing, usually in seven to ten minut Where this second ring does not occur in the fig signifies that the wheal never grew larger than original "peau d'orange": this will be found y with the salt controls, for none of the proteoses ed to grow larger. The broken line, where it ars, signifies, as in Fig. 1, the outer limit of the rounding erythematous flush. As with the pro se reactions in Fig. 1, the whealing and flushing s usually slight as compared with authentic itive skin reactions.

---

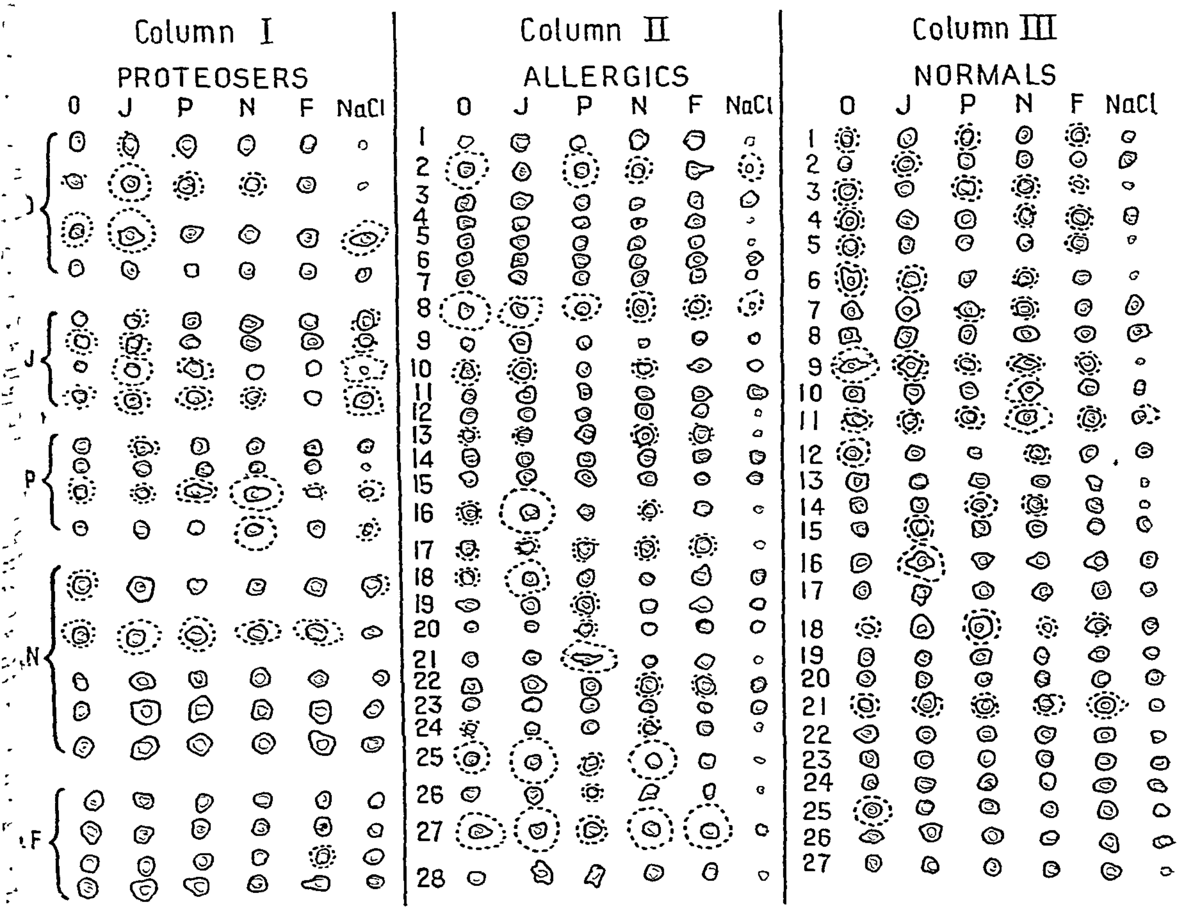
[4] This is probably due to the hay-fever proteose becoming more toxic with the passage of time; whereas Columns I. and II. were tested soon after receiving the proteose from Oriel, Columns III. and IV. were tested some four months later by which time the hay-fever proteose had become decidedly milky and, as this figure suggests, presumably more toxic though still sterile.

[5] In Fig. 1 an attempt was made to guard against this er by deliberately injecting the fluids in a different order in succes subjects. Thus for the first case the order of injections fr above downwards might be hay-fever proteose, normal sal and control proteose; for the next this might change to con proteose, hay-fever proteose, and normal saline; and so Thus each rival fluid would get the better station in turn.

[6] I do not think this helps us very much for even the nor saline in most of the subjects tends to spread during the ten minutes or so (see the "NaCl" reactions in all three colum but I recorded this because I found that my colleagues at Gu Hospital were doing so. It enables one to see to some ext how comparable were the mechanics of the various inject beside being able to say if there is any increase of wheal bey the first swelling of the skin caused by the injection itself.

olumn I. of Fig. 2 has been headed "Proteosers," l shows all the tests done on the five persons who yielded the five proteoses. They are indicated in the left margin by their already mentioned initial letters O, J, P, N, and F; and the proteoses obtained from these people are indicated at the head of each of the three columns by the same five initial letters, with the addition of "NaCl" signifying the normal saline control. It will be seen that the individuals O, J, P, and F were each of them tested four times over with each of the six fluids, while N was tested five times. The tests were made at different times of day and night, sometimes with three or four days in between; also, since the repetitions gave me opportunity of varying the areas, some were done on the usual sites of forearm or above the knee, while other tests were done on the calf of the leg, or across the chest, stomach, or shoulders. The more erythematous records—e.g., the second series on N—were obtained from stomach or chest. All this was done to eliminate the time and locality factors brought forward by Dr. Barber in his letter in THE LANCET of Dec. 5th, 1931, answering mine of the week before.[7] In Columns II. and III. the men were tested on the forearm, and the women and children on the anterior surface of the thigh.

FIG. 2.



If Oriel's story is correct then Miss "O" should react four times to O proteose, Master "J" should react to J proteose, and Mr. "P" to P proteose. All other skin tests in this figure, whether proteosers, allergics, or normals, should be negative save where an allergic person in Column II. happens to share the same allergic antigen with Messrs. "O," "J," or "P."

I think that anyone examining Fig. 2 carefully will find it impossible to detect any such specific reactions on the part of O, J, and P to their autogenous proteoses. I think there can be no failure to detect that so far as reactions can be said to occur they occur with everybody to all proteoses—in other words, that the proteoses are toxic.

Of the wellnigh 500 "reactions" shown in Fig. 2 there was only one which seemed to me to be quite of the pollen-hay-fever intensity, and this was allergic No. 21 to P proteose; possibly also normal No. 9's reactions to O and J proteoses might be placed in the same category. These three reactions have been distinguished in the figure by shading-in the erythematous area, but the three urticarial wheals (especially that of allergic No. 21) were also more intense than with the other so-called reactions in the figure. I cannot tell the significance of this.

---

[7] I believe this time variant, when it occurs, to be largely due to the psychological factor in the man under observation, but it is perhaps worth controlling when trying to detect minute differences of reaction.

Many of the reaction sites of people in all three columns swelled up again in from 12 hours to three days after the injection, becoming red, swollen, and painful. All these delayed reactions disappeared again after about the length of time which it had taken them to show up. This did not occur more with the proteosers than with the allergics and normals, and there was no indication of specific delayed reactions of the proteosers to their autogenous proteoses. To avoid confusion, these reactions are not indicated in the figure; they were not the criterion selected by Oriel in his claim of specificity, and they were not all of them recorded in my notes. Presumably they are more akin to the Pirquet tubercle reactions or to the Schick test, &c.

In corroboration of my failure to find specific skin reactions with the autogenous proteoses, I am permitted to say that Dr. George Bray, working for the Asthma Research Council at Great Ormond-street Hospital, has obtained results which, he says, tally so exactly with mine that he does not think it worth while publishing them. I may also perhaps direct attention to the researches on the alleged specificity of proteose reported by Prof. Murray Lyon and co-workers.[8]

CONCLUSIONS.

1. Oriel's "proteoses," no matter whence obtained or on whom tested, show a fairly constant toxic reaction within a few minutes of injection into the skin. (They may also show a delayed reaction.) (2) I can detect no trace of the specific skin reactions claimed by Dr. Oriel. (3) An immunotherapy based on this alleged specificity has to my mind no scientific foundation. (4) Negative researches are dreary work; I hope I am now taking my leave of proteose.

THE DURATION OF THE RED LOCHIA.

By Chassar Moir, M.D., F.R.C.S. Edin.,

REGISTRAR TO THE OBSTETRIC UNIT, UNIVERSITY COLLEGE HOSPITAL.

It is usually believed that the blood-stained vaginal discharge which follows a normal confinement lasts for a period of about seven days, and that the persistence of this discharge for more than ten days is an indication of an abnormality such as retained pieces of placenta, subinvolution, or retroversion of the uterus. The following extract from a standard text-book[9] is representative of the usual teaching:—

> "In the average case with the mother suckling the child the lochia remain bright red for three or four days, then become pinkish-brown for three or four days; at the end of eight, nine, or ten days they lose their colour and are represented by an almost transparent fluid. . . . The lochia may remain coloured for rather longer than usual in cases in which the mother does not suckle her child."

It has long seemed to me that the cases which obey this rule are far outnumbered by the exceptions, in which the coloured lochia persist for some weeks without any discoverable abnormality. In order to obtain more exact information on these matters I have made special note of the duration of the lochia and the condition of the uterus in 250 patients whom I have personally examined at the postnatal clinic of University College Hospital.

The great majority of patients who attend this clinic have been delivered in the hospital five or six weeks previously, and each patient, before discharge from hospital, has been examined. and any abnormality, such as retroversion of the uterus, corrected. It follows that the proportion of normal cases in the postnatal clinic is very high. This is particularly so because many patients known to be debilitated while in hospital are sent to a convalescent home, and may not report to the postnatal clinic for some months. Such cases have not been included.

In this investigation no attempt was made to distinguish between lochia rubra and lochia serosa; each patient was carefully questioned on the duration of a red vaginal discharge, and the answer noted. The amount of the discharge was not taken into account because patients vary so much in their ability to describe quantities in accurate terms. A daily red or reddish-brown discharge sufficient to necessitate the wearing of a diaper was taken as the criterion of the duration of the red lochia for the purpose of this investigation. In a great many cases it was found that during the last three or four days in hospital the patient ceased to have a red discharge, but that with the resumption of household duties this discharge reappeared. In such cases the short interval was ignored, and only the final dis appearance of the coloured lochia was taken int account. Each examination included questionin the patient with regard to general health and breas feeding, after which a general physical examinatior with special reference to the pelvic organs, wa made.

TABLE I.

Total number of cases examined 250
Average duration of coloured lochia .. .. 24 da

Duration of red lochia.	Number and percentage.	Duration of red lochia.	Number a percentag
Under 10 days..	35 (14)	22–28 days ..	63 (25)
11–14 ,, ..	40 (16)	29–35 ,, ..	50 (20)
15–21 ,, ..	47 (19)	Over 35 ,, ..	15 (6)

Table I. shows that the duration of the colour lochia was variable, but that in the great majori of cases it was far in excess of the "normal" ten-d period. In 70 per cent. of patients it exceed 14 days, and in 51 per cent. it exceeded three wee

FACTORS INFLUENCING DURATION.

The question at once arises as to the part play by abnormal uterine conditions in bringing abo this persistence of blood-stained discharge.

Subinvolution.—The uterus five weeks after delive is not fully involuted, and may be best describ as being one and a half times the size of a norm parous uterus. With a little experience it is easy recognise the usual size and to pick out those ca in which the uterus is bulkier than usual. Such ca numbered 34. Subinvolution when combined wi retroversion was not included in this group.

TABLE II.

Subinvolution of the uterus (without retroversion)—
Number of cases 34
Average duration of coloured lochia .. 25·2 d

Duration of coloured lochia.	Number and percentage.	Duration of coloured lochia.	Number percentag
Under 10 days..	5 (14·7)	22–28 days ..	4 (11·7
11–14 ,, ..	6 (17·7)	29–35 ,, ..	6 (17·7
15–21 ,, ..	9 (26·4)	Over 35 ,, ..	4 (11·7

It will be seen that, although there was an unusua long duration of coloured lochia in a few cases, t *average duration for this group* was not apprecial rent from that of the normal group. In many s the duration was unusually short; hence it be assumed that subinvolution by itself is not a e of a prolongation of coloured lochia.

---

[8] Brit. Med. Jour., Jan. 23rd, p. 136.

[9] Midwifery. By Ten Teachers. London, 1931 (4th ed.), p. 525.

etroversion of the Uterus.—These cases are few, use retroversion is corrected before the patient es hospital, and pessaries are used to maintain correct position in the first few months of the rperium. Not infrequently retroversion is found e associated with subinvolution. Such cases are uded under the heading of retroversion.

TABLE III.

oversion of the uterus (with or without associated ibinvolution)—

Number of cases	25
Average duration of coloured lochia ..	21·6 days

uration of ured lochia.	Number and percentage.	Duration of coloured lochia.	Number and percentage.
ler 10 days ..	8 (32)	22–28 days ..	6 (24)
11–14 ,, ..	1 (4)	29–35 ,, ..	4 (16)
15–21 ,, ..	5 (20)	Over 35 ,, ..	1 (4)

The cases of retroversion recorded in this table w an average duration of coloured lochia which lightly less than that of the total group (21·6 days l 24 days).

Effect of Suckling.—It is frequently stated that kling promotes the involution of the uterus, and versely that the uterus of a woman who does not kle her child involutes at a slow rate. The great jority of hospital patients nurse their babies, and only 29 cases were recorded where no suckling had ken place. These were mostly women whose children d been born dead or had died soon after birth. Table IV. shows that in the 29 recorded cases me degree of subinvolution was present in four ses. There was no undue prolongation of the loured lochia in this group; the average duration as actually slightly less than that of the total mber of cases (20·8 days, and 24 days).

TABLE IV.

Total number of women who did not suckle ..	29
Number found to have subinvolution of uterus ..	4
Average duration of coloured lochia	20·8 days

Duration of coloured lochia.	Number and percentage.	Duration of coloured lochia.	Number and percentage.
Under 10 days ..	7 (24)	22–28 days ..	9 (30·9)
11–14 ,, ..	3 (10·3)	29–35 ,, ..	4 (13·5)
15–21 ,, ..	6 (20·6)	Over 35 ,, ..	—

Parity and Age.—The cases were further divided into groups to show the effect of parity, and of age, in determining the duration of the lochia.

Primiparous patients	170
Average duration of coloured lochia	23·5 days
Multiparous patients	80
Average duration of coloured lochia	25·5 days

Age.	Number.	Average duration of coloured lochia.
25 years and under ..	117	24 days
26–35 years	103	24·5 ,,
35 and over	31	23·8 ,,

Thus, neither parity nor age has any appreciable effect in altering the duration of the coloured lochia.

CONCLUSIONS.

1. The duration of a coloured vaginal discharge following childbirth in 250 hospital patients varied considerably, but in the great majority of cases it far exceeded the supposed normal time limit. The average duration was 24 days. 2. The average duration of the coloured lochia in cases of uterine subinvolution and of retroversion was not greater than the average of the total number of cases. 3. In this series there were 29 cases in which suckling was not carried out. Those cases did not show any prolongation of the coloured lochia. 4. Age and parity had no appreciable effect on the duration of the coloured lochia.

CLINICAL AND LABORATORY NOTES

CASE OF APPARENT URINARY MYIASIS.

BY J. GORDON, M.D. LEEDS, D.P.H.,
LECTURER IN BACTERIOLOGY, UNIVERSITY OF LEEDS;
AND
G. ROSEMONT, M.B., B.SC. LEEDS.

CASES of urinary myiasis are rare, and in those hat have been reported the larva concerned is either hat of the lesser house-fly, *Fannia canicularis*, or f the latrine fly, *F. scalaris*. At any rate in the ext-books I have consulted there is no reference o the appearance of the larva of the common house-fly, *Musca domestica*, in the urinary tract. (Byam and Archibald: "The Practice of Medicine in the Tropics," 1921. Patton: "Insects, Mites, Ticks, and Venomous Animals of Medical and Veterinary Importance," 1929. Castellani and Chalmers: "Manual of Tropical Medicine," 1919.)

The patient was aged 50, male, and suffering from chronic parenchymatous nephritis. On passing urine into a chamber pot he felt a sudden sharp pain and observed that he had passed three larvæ. The following night (7 P.M.) he experienced the same pain on passing water and passed a single larva. On this occasion he reported it to his medical man. The larva was that of *M. domestica* in its final stage, and curiously transparent; the latter fact and the season of the year (December) in which the larva was passed suggested that it was not of accidental occurrence in the vessel. It is not known how larvæ gain access to the bladder in the male, but the suggestion has been made that it is by boring through into this position from the alimentary canal.

The larva was submitted to Prof. D. Keilin, F.R.S., who confirmed the diagnosis. We are indebted to Dr. Ll. Lloyd, reader in entomology, University of Leeds, for his assistance in the discussion of the case.

RECURRENT RUPTURED TUBAL GESTATION.

BY JOHN C. HODGSON, M.D. EDIN.,
HONORARY SURGEON TO ASHFORD HOSPITAL, KENT.

RECENT correspondence in these columns [1] prompts me to describe this case in the belief that the occurrence of ruptured tubal pregnancy twice within six months in the same woman may be worthy of record.

Mrs. A., a nervy woman, aged 32, with one child of 6 years, walked into the surgery on August 27th, 1931, complaining of severe pain in the right side, and scanty menstruation which was about a week been distinguished in the figure by shading-in the erythematous area, but the three urticarial wheals (especially that of allergic No. 21) were also more intense than with the other so-called reactions in the figure. I cannot tell the significance of this.

---

[1] THE LANCET, Jan. 16th, p. 132; Jan. 23rd, p. 209; Jan. 30th, p. 261; Feb. 6th, p. 315; Feb. 13th, p. 371.

Many of the reaction sites of people in all three columns swelled up again in from 12 hours to three days after the injection, becoming red, swollen, and painful. All these delayed reactions disappeared again after about the length of time which it had taken them to show up. This did not occur more with the proteosers than with the allergics and normals, and there was no indication of specific delayed reactions of the proteosers to their autogenous proteoses. To avoid confusion, these reactions are not indicated in the figure; they were not the criterion selected by Oriel in his claim of specificity, and they were not all of them recorded in my notes. Presumably they are more akin to the Pirquet tubercle reactions or to the Schick test, &c.

In corroboration of my failure to find specific skin reactions with the autogenous proteoses, I am permitted to say that Dr. George Bray, working for the Asthma Research Council at Great Ormond-street Hospital, has obtained results which, he says, tally so exactly with mine that he does not think it worth while publishing them. I may also perhaps direct attention to the researches on the alleged specificity of proteose reported by Prof. Murray Lyon and co-workers.[8]

CONCLUSIONS.

1. Oriel's "proteoses," no matter whence obtained or on whom tested, show a fairly constant toxic reaction within a few minutes of injection into the skin. (They may also show a delayed reaction.) (2) I can detect no trace of the specific skin reactions claimed by Dr. Oriel. (3) An immunotherapy based on this alleged specificity has to my mind no scientific foundation. (4) Negative researches are dreary work; I hope I am now taking my leave of proteose.

THE DURATION OF THE RED LOCHIA.

By Chassar Moir, M.D., F.R.C.S. Edin.,
REGISTRAR TO THE OBSTETRIC UNIT, UNIVERSITY COLLEGE HOSPITAL.

It is usually believed that the blood-stained vaginal discharge which follows a normal confinement lasts for a period of about seven days, and that the persistence of this discharge for more than ten days is an indication of an abnormality such as retained pieces of placenta, subinvolution, or retroversion of the uterus. The following extract from a standard text-book[9] is representative of the usual teaching:—

> "In the average case with the mother suckling the child the lochia remain bright red for three or four days, then become pinkish-brown for three or four days; at the end of eight, nine, or ten days they lose their colour and are represented by an almost transparent fluid. . . . The lochia may remain coloured for rather longer than usual in cases in which the mother does not suckle her child."

It has long seemed to me that the cases which obey this rule are far outnumbered by the exceptions, in which the coloured lochia persist for some weeks without any discoverable abnormality. In order to obtain more exact information on these matters I have made special note of the duration of the lochia and the condition of the uterus in 250 patients whom I have personally examined at the postnatal clinic of University College Hospital.

The great majority of patients who attend this clinic have been delivered in the hospital five or six weeks previously, and each patient, before discharge from hospital, has been examined, and any abnormality, such as retroversion of the uterus, corrected. It follows that the proportion of normal cases in the postnatal clinic is very high. This is particularly so because many patients known to be debilitated while in hospital are sent to a convalescent home, and may not report to the postnatal clinic for some months. Such cases have not been included.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE.

ECTION OF THE HISTORY OF MEDICINE.

a meeting of this section held on March 2nd. h Dr. R. O. Moon, the President, in the chair, a er on the history of the

ntroduction of Biochemistry into Medicine

read by Dr. W. Langdon Brown. It was, he l, Paracelsus who was generally regarded as the ner of physiological chemistry; for it was he who rded Galenic tradition and taught chemical rapeutics. Additions to our knowledge of digestive cesses and the discovery of carbon dioxide were de by Van Helmont, who, however, had laid ater store by his speculative doctrines than by se practical achievements. He was the founder the iatrochemical school, which reached its zenith h Sylvius. Although ignorant of the fundamental ts of chemical science the iatrochemists had empted in vain to explain the functions of the ly entirely by reference to chemical operations. om them rose a school which attempted to explain the phenomena of the body upon mechanical nciples—the iatromathematical school, led by relli. Here was an example of the unwisdom premature attempts to state medicine in terms of mistry and physics. The danger was recurrent d there was to-day in certain quarters a tendency push biochemistry to unjustifiable conclusions, led a new school of iatrochemistry. In the ne way, although to settle down under the vitalistic potheses merely spelt obscurantism, the equation d the graph were so mentally satisfying, things came out" so neatly that there was a distinct mptation to apply mathematics too soon to clinical rk. The reaction from the iatrochemists had soon ne with Stahl who stood forth at the close of the venteenth century as the founder of animism. hich doctrine had maintained itself in many minds rough two succeeding centuries and existed still.

Dr. Langdon Brown then turned to the history of the roduction of certain biochemical methods and ideas to the diagnosis and treatment of disease. hough in 1777 Stevens had studied digestion foodstuffs in perforated silver balls by inducing stone swallower to swallow and regurgitate them, e first clear picture of gastric digestion had been ven by Beaumont's observations on Alexis St. Martin 1822. Two years later Prout had shown the esence of hydrochloric acid in the gastric juice. e gastric sound first employed by Leuke in 1883 d the test breakfast devised by Ewald had soon ought the recognition of the absence of hydrochloric acid in gastric carcinoma and its excess in ptic ulcer. But the introduction of the method of ctional test-meals had given an entirely new point f view, dynamic rather than static and therefore pically biochemical. Thus the importance of e bactericidal properties of hydrochloric acid had en learnt and the discovery made of achlorhydria in to 6 per cent. of apparently healthy individuals. An achlorhydric diathesis had been established as a ctor in what the speaker had called predestination in disease.

Pepsin was discovered by Brücke in 1851 and trypsin by Danilewski in the following year. Kühne had shown that the more profound disintegration of the protein molecule by the latter enzyme was responsible for the colour reaction with bromine water. Neumeister had given the name of tryptophan to this, merely implying that it was an indication of tryptic activity. There the matter had rested until 1901 when Hopkins and Cole had isolated tryptophan and had shown it to be an aromatic body and an important constituent of many proteins. This was the starting-point of the researches of the greatest practical value, for in 1906 by depriving rats of tryptophan in their diet Hopkins had shown that they failed to grow. From these experiments had come the recognition of the importance of the accessory food factors, resulting in the revolution of our conceptions and treatment of deficiency diseases. A by-product of the study of tryptic digestion had proved of far-reaching importance, for when these amino-acids had been identified they or their intermediate products were in certain circumstances found in the urine instead of their normal end-products. The occurrence of the abnormal excretion of such substances was usually congenital and familial. On this foundation Sir Archibald Garrod had built up his work on the inborn errors of metabolism. Such conditions as alkaptonuria, pentosuria, cystinuria, and porphyrinuria were admittedly rare and usually almost symptomless, but through them the conception of diatheses had been reinstated on a new and scientific basis on the lines of Mendelian inheritance.

It would be difficult, he said, to assess the value of biochemistry in our knowledge of nephritis, for while it had revealed the inadequacy of the classifications based on morbid anatomy it had not replaced these by any clear-cut conceptions. Richard Bright's description in 1827 of the disease associated with his name showed that he had appreciated the pre-renal factors in nephritis. Gradually those substances which the kidney failed to excrete had been found to be of greater importance than those which it allowed to escape. Methods for the quantitative estimation of urea in urine had been introduced by Ludwig, Doremus, and Dupré in 1853 and the following years. But for some time the results were misinterpreted because the amount of protein in the diet was not then known to influence the amount of urea in the urine. A clear idea of renal efficiency necessitated a comparison of the urea in the blood and the urine—a comparison first made by Widal and Javal in 1905. The recognition of urea retention in certain cases of nephritis and not in others had led to the distinction by the French school between hydræmic and azotæmic nephritis. But biochemistry to-day was chary of accepting the idea of a watery dilution of the blood volume. Rowntree and his co-workers in 1929 had shown that in glomerulo-nephritis and nephrosis the blood volume was within normal limits except that it might be slightly raised where there was accompanying anæmia. The induction of diuresis had no constant effect on blood volume; evidently the excess of fluid had to be drawn from the tissues.

The history of the biochemistry of lymph formation and œdema started in 1844 when Ludwig put forward a physical conception of urinary secretion, the blood pressure being the motive power for the filtration through the glomerular epithelium, while reabsorption occurred in the tubules. Heidenhain in 1866 had strongly opposed this view, regarding glomerular activity as a true secretion. When Ludwig discovered overdue. On examination a tender pulsatile mass was found in the right fornix. At operation a ruptured tubal pregnancy was found in the ampullary portion of the right tube with some bleeding into the peritoneal cavity. The right tube was removed and she made an uninterrupted recovery.

On Feb. 8th, 1932, she again walked into the surgery, complaining of slight pain on the left side, and an excessive period with clots, which had gone on for over a week. She last had an ordinary period at Christmas time. Vaginal examination was done with difficulty because of the nervous state of the woman, and appeared negative. The uterus did not seem palpably enlarged, and while the cervix seemed a little soft it was not patulous. She was slightly anæmic, and was given some ergot and told to go home to bed, but to send if the pain returned. She did not send for 72 hours, when I found her semi-moribund lying in bed with all the signs of advanced internal hæmorrhage. She was hurried to the operating theatre, where the peritoneal cavity was found full of blood-clot, the uterus about the size of a tangerine orange, and a tubal mole extruding from a tear in the ampullary portion of the left tube. The left tube was removed, and on account of her critical condition gum saline was given intravenously at the end of the operation. She again made an uneventful recovery.

The left tube was sent to Maidstone pathological department, where they were unable to observe any abnormality to account for her condition.

I may say that Cullen's "umbilical sign" was not present on either occasion.

PERSISTENT ALLANTOIC DIVERTICULUM CAUSING INTESTINAL OBSTRUCTION.

By J. E. A. Boucaud, M.B. Lond.,
RESIDENT SURGEON, COLONIAL HOSPITAL, PORT OF SPAIN;
AND
J. A. Waterman, M.B. Glasg.,
GOVERNMENT MEDICAL OFFICER, TRINIDAD.

A MAN, aged 53, was admitted to the Colonial Hospital, Port of Spain, on Oct. 4th, 1931, at 7 P.M., with the history of having drunk some coconut water the previous evening, and of vomiting and abdominal pain since.

On admission.—Abdomen was soft with slight tenderness in the epigastrium. He had a left inguinal hernia, but there was neither incarceration nor strangulation. Per rectum nil. Temp., 99° F.; pulse-rate, 88; respirations, 28. He vomited several times during the night. Enema produced a constipated stool and some flatus.

On Oct. 5th, at 6 A.M., temp., 98·4°; pulse-rate, 58; respirations, 20. On examination at 9 A.M. nothing abnormal was noted in heart or lungs. The abdomen was slightly distended in the epigastric region. Liver dullness not reduced. He complained of slight discomfort in the region of the umbilicus. But he continued to vomit yellowish fluid. At 2 P.M. the general condition was good. An enema resulted in a small motion.

On Oct. 6th, at 6 A.M., temp., 97·8°; pulse-rate, 58; respirations, 20. He had vomited three times during the night. Vomitus at 5 A.M. had a definite fæcal odour. The epigastrium was still distended. Per rectum collapsed gut was palpated. The stomach was washed out and the fluid returned was definitely fæcal. Operation was advised but refused. Turpentine and ox-gall enemata were tried with little success. But his general condition remained very good until the evening of Oct. 8th. At 8 P.M. his vomitus was fæcal in character. The pain in his abdomen became more severe. At 10 P.M., temp., 97·6°; pulse-rate, 92; respirations, 28.

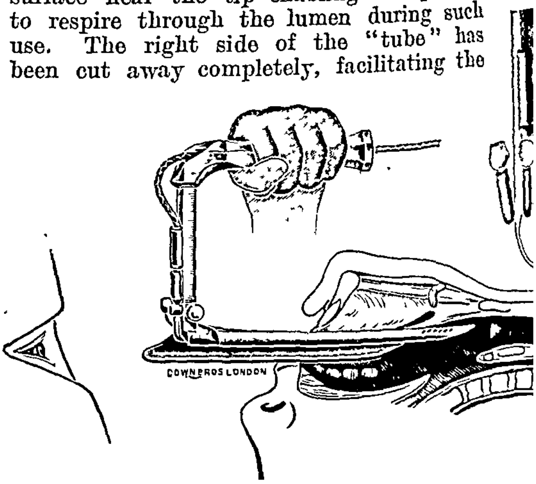
On Oct. 9th he consented to have the operation. Before the anæsthetic his stomach was washed out. A right paramedian incision was made. A portion of the small intestine, mesentery excluded, was caught in a circular opening in the wall of the bladder. This opening was due to an invaginated proximal end of a persistent allantoic duct. The intestine distal to this was quite collapsed, but as soon as the obstruction was relieved dilatation was effected. There was no gangrene. The site of pressure on the small intestine was not ulcerated, and the circulation was good. A Lembert suture was introduced to bury the line of constriction. The persistent allantoic diverticulum was evaginated and sutured to the peritoneum of the anterior abdominal wall, and the abdomen closed.

The patient made an uninterrupted recovery and was discharged well on Oct. 23rd.

NEW INVENTIONS

ILLUMINATED DIRECT LARYNGO-PHARYNGOSCOPE.

THE instrument here described I have been usin for a considerable time; it is longer than the usua pattern and it has definite advantages. It is adequat for the largest adult; but owing to the tapering o the end, is convenient for children of two years ol For examination of or operation on the larynx i gives very good exposure, and the tip can be passe between the vocal cords; it is useful also as an upp œsophageal speculum, and will reach all forei bodies in the common site of impaction, imm diately below the cricoid, the slotting of the ventr surface near the tip enabling the patient to respire through the lumen during such use. The right side of the "tube" has been cut away completely, facilitating the passage of instruments. An anæsthetic tube built into the left wall, abolishing the need fo separate anæsthetic tube, and delivering the vap well down the lumen. The "tube" of the instrum is of stainless steel, 20 cm. long, and 16 by 20 m internal diameter; the right wall is absent, a s of 1 cm. wide being left. Commencing at 8 cm. fr the tip the width is gradually tapered to 8 mm. at tip, which is blunt; at the same time the vent wall is discontinued, so that the distal 5 cm. definitely a concave spatula, the concavity gradu lessening toward the tip. Illumination is by me of a Jackson-type lamp carrier, taking the stand lamps (2·5 milliamperes) which are carried at distal end. The handle is also of the Jackson ty but hollow, so that the lamp-flex is carried well aw from the upper end during use.



Messrs. Down Brothers, Ltd., St. Thomas's-stre London, S.E., are the makers of the instrument.

E. WATSON-WILLIAMS, *M.C.*, F.R.C.S

breath or found they could breathe more easily the head was raised higher than usual. If such nor respiratory difficulties had not been recognised, barrassment would probably become evident der anæsthesia, and especially during the second age. Tracheotomy might then be unexpectedly cessary with risks which would not otherwise have en present. Lung complications accounted for the ajority of fatalities. Oral sepsis must be vigorously rrected before operation on the throat, and though is might not be the anæsthetist's province, he was t uncommonly held largely responsible for pulonary complications. After removal of teeth e gums must have soundly healed before the eration. Most of the subjects of serious throat perations were at or past middle age, and their ouths were seldom in really good condition. Packs aked in cocaine and adrenalin were employed to nder the mucous membrane analgesic, and they ere instrumental in lessening the amount of general næsthetic required. To make a tracheotomy pening in these cases was better than to carry ut endotracheal anæsthesia; there was always he possibility that the tube might carry infection, r at its insertion might dislodge a portion of growth nd so disseminate it in the lungs. A further reason was that a tube restricted the surgeon's field of ctivity.

For severe throat operations the anæsthetic of hoice was chloroform with oxygen. Dr. Morris aid he was aware of the existing prejudice against hloroform, and he was of course against its indiscriminate use in the wrong type of case. Mr. Wilfred Trotter had told him that during the time he had been performing these operations he had never had anxiety on account of the chloroform anæsthesia, and that was the speaker's experience over 20 years. There must be a free airway and plenty of oxygen. During the operation the patient was noticeably free from any tendency to congestion and hæmorrhage, and it was usual for him to leave the table with the coughing reflex present and the pulse little faster than at the beginning of the operation. In none of his cases had there been delayed chloroform poisoning. With modern apparatus the supply of oxygen could be kept separate from that of chloroform, and mostly no more than 3 to 4 drachms of chloroform per hour was required.

After tracheotomy the regular to and fro breathing was replaced by a different type—namely, one in which long periods of apnœa were followed by periods of dyspnœa—and this might persist throughout the operation, afterwards giving place to the normal breathing. Unless surgeon and anæsthetist were aware of this, they were apt to become alarmed and to perform artificial respiration in apnœic periods.

In the large group of cases in which the operation was away from the opening in the larynx and there was no danger of obstruction, one of the intratracheal methods was best. He preferred to apply the vapour under low pressure through a soft tube, which provided for a return airway and allowed of packing off the larynx. Passage of the tube by the nasal route had many advantages. For operations in the hypopharynx and on the cords and in which tracheotomy was necessary, he thought it might be better for the patient if the tracheotomy were always done under local anæsthesia and if time was allowed for him to accustom himself to that type of breathing, rather than for both procedures to be done under general anæsthesia at one time.

DISCUSSION.

Dr. **Ll. Powell** agreed with Dr. Morris's general plan, but preferred to use a bellows rather than a stream of oxygen to convey the chloroform.

Mr. **Lionel Colledge** agreed, as an operator in these cases, that the main principle was that there should be no respiratory obstruction. Tracheotomy was not necessary in every case. If respiratory obstruction was allowed to occur, it was usually too late to do tracheotomy, for the damage had already been done; the tracheotomy might restore the breathing, but after that the anæsthesia would not proceed quietly again, and if there was a pulmonary complication in that type of case it was not due to the anæsthetic as such but to the respiratory obstruction. He saw no object in using general anæsthesia for tracheotomy; it was much simpler and easier under a local anæsthetic, and from the beginning the anæsthetic could be administered through the tracheotomy tube. He had never seen trouble due to the use of chloroform. Delayed chloroform poisoning was relatively much more likely to develop in children and young adults. When the entire larynx had to be removed, if there was no obstruction—though often there was—it was useful at an early stage of the operation to open the cricothyroid membrane, put in a laryngotomy tube, pass the anæsthetising material through that, and remove the laryngotomy tube with the larynx. That obviated the necessity of doing a preliminary tracheotomy, and one had a clean wound, without risk of sepsis from a preliminary operation.

Dr. **A. L. Flemming** suggested it might be useful to add CO_2 to the mixture to overcome the apnœic phase after the performance of tracheotomy.

Mr. **John Hunter** endorsed all that Dr. Morris had said as to the use of chloroform in these throat cases. He found that the old men who usually required these operations took chloroform well, especially as the amount needed was materially reduced by the introduction of cocaine into the open larynx, and if morphia was used towards the completion of the operation this also lessened the required dose of chloroform. From the operative standpoint he did not see the need for the tracheotomy to be a separate preliminary procedure; it should be done at the same time as the main operation. But if obstruction existed, tracheotomy was required and the patient should be returned to bed to await the operation proper.

Sir **Francis Shipway** said he was glad to hear chloroform recommended. Where a tracheotomy tube was used in these cases it was impossible to give a fatal dose of chloroform. He had seen respiration arrested by a heavy dose, but though nothing was done it restarted. Nor did he think a continuous stream of oxygen constituted a danger. Prof. Buckmaster's work showed that during chloroform anæsthesia oxygen tension was reduced by 40 per cent., so there was no danger of over-oxygenating. Oxygen was needed because during chloroform administration there was a definite anoxæmia.

Mr. **T. Ritchie Rodger** thought there was no sufficient reason for believing that injection of adrenalin was dangerous when chloroform was used.

Dr. **J. Blomfield** said that the point of importance in regard to the use of adrenalin in these cases was the difference in its action when injected and when it was applied on a swab. In Dr. Morris's paper the reference was to the use of adrenalin on swabs. These caused no trouble, and that was also the speaker's experience. The trouble which had occurred with that urea had a diuretic effect even after the blood pressure had been lowered by section of the spinal cord, he had come to regard glomerular activity as due to osmosis through a semipermeable membrane. These protagonists had been also engaged in a similar controversy over the allied subject of lymph formation. Ludwig had explained lymph formation by diffusion, but Heidenhain, having observed a friend afflicted by urticaria after eating crab, had described two classes of lymphogogues, one organic such as extract of crab's muscle and the other crystalloid substances; he had set up a secretory hypothesis of lymph formation. Then Starling in 1896 had overthrown this hypothesis by explaining Heidenhain's first class of lymphogogues as being toxic to the capillary endothelium while the second acted by osmosis.

Widal's theory of salt retention in the tissues as the cause of œdema had been advanced in 1902, but recent work put forward by Izod Bennett interpreted the salt retention as the result and not the cause of œdema. The most usually accepted explanation of renal dropsy to-day was an alteration of the affinity of the tissue cells for water as the result of an altered metabolism. The idea of anaphylaxis was introduced by Richet in 1900 as the antithesis to prophylaxis. In 1906 von Pirquet introduced the term allergy to include all conditions of altered reactivity. A more precise chemical connotation had been given by Sir Henry Dale's researches on histamine in 1910, followed by Sir Thomas Lewis's observations on the vascular reactions in the skin. A substance toxic to everyone was apparently only liberated in the tissues of certain people in answer to stimuli which were innocuous to everyone else. Lewis had shown that for one of the reactions he observed, the sensory nerve-fibres had to be intact while another was independent of the nerve-supply. Dale had observed that adrenalin directly antagonised histamine and that the vagal and sympathetic stimulation of the heart were indirect, being mediated through the liberation of chemical substances. Adrenalin was the best antidote to an allergic crisis because it neutralised histamine and stimulated the sympathetic, or inhibitory, nerves to plain muscle. For Langley's great generalisation in 1901 had taught that the effect of adrenalin on any part was the same as stimulation of the sympathetic to that part. Here was clear instance of the transformation of a nervous into a chemical action; the pituitary diencephalic apparatus provided others. This relationship between the chemical and nervous factors in the reaction of the organism to disease might be regarded as the actual growing point of knowledge.

DISCUSSION.

Sir **Archibald Garrod** spoke of William Hyde Wollaston, that man of wide attainments, physician, botanist, chemist, physicist, who had described the structure of all the urinary calculi except those of uric acid (which had been previously described). He said that William Prout had maintained that pure chemistry provided by the chemist was of little use to medicine; it was necessary for the physiologist to make himself a chemist. He had believed that chemistry would guide the physician as anatomy did the surgeon. Prout had recognised that urea and carbon dioxide were formed by the breakdown of tissues—facts which were rediscovered by Liebig. He also discovered the hydrochloric acid in the gastric juice, and seemed to have had a glimmer of the conception of enzymes.

Sir **Gowland Hopkins** said that as one whom fate and circumstance had detached from immediate clinical interests he could acknowledge the great debt which chemistry owed to medicine. Just at the turn of the last century, he said. circumstances combined to give a special impetus to biochemica studies; the great advance in the chemistry o proteins, a realisation of the existence of hormones and recognition of the functions of the endocellula catalysts in metabolism. To this impetus the work and thought of the previous speaker notably contributed He went on to cite Liebig as illustrating in his worl and teaching the circumstance that those who ar concerned with the borderlands of knowledge must in order to obtain the highest success, cultivate a far as is humanly possible the thought proper t both sides of the border. If Liebig had but had th biological training or, otherwise, had possessed th remarkable innate biological instincts of Pasteu his genius would have given biochemistry a statu for which it had long to wait.

Sir **William Willcox** referred to the great assistanc biochemistry had rendered medicine in the twentiet century; the blood-urea in uræmia and suga tolerance curves were examples of the aid that ha been given to diagnosis and prognosis. Adrenali and thyroxin had been synthesised. The toxicologi had been enabled to think of the action of a poiso after absorption instead of observing its effects the stomach and intestines.

Prof. **E. C. Dodds** gave an account of the work Hoppe-Seyler. He had crystallized hæmoglobin, ha shown it to be a protein containing iron, and relate to the blood-pigments of other animals. He suggeste that hæmoglobin was the carrier of oxygen an demonstrated its absorption spectrum.

Dr. **T. Watts Eden** remarked that Owen Ree F.R.S., must have done much of the chemistry f Bright.

Dr. **T. Izod Bennett** gave an account of the ear history of nephritis. In 1829 Bright had not the low content of protein in the blood of œdemato patients but it was not till 1914 that Epstein broug out the importance of this observation.

Dr. **A. P. Cawadias** said that the idea of bi chemistry was introduced in the fifth century B. when Hippocrates first spoke of the modifications the humours. Although he considered changes blood, bile, and urine, he had not based his diagno on biochemistry because his knowledge was incomplete. With the vast progress of the scien our aim should now be to detect and treat the modific tion of the chemistry of the organs which must preced a lesion.

SECTION OF ANÆSTHETICS.

At its meeting on March 4th, with Dr. G. **Ramse Phillips**, the President, in the chair, this sectio discussed

Anæsthesia for Major Throat Operations.

Dr. **C. W. Morris** said these operations presented many difficulties. Respiration might be hindere by obstruction of the airway by the growth, an there was a grave threat of pulmonary complications The surgeon must be allowed the maximum freedo for his manipulations—especially in lateral pharyngo tomy. Degrees of embarrassment short of actu stridor and cyanosis must be recognised and minimised A proportion of patients would not admit they ha experienced difficulty in breathing, indeed they migh not have been aware of it; only by close questionin could it be ascertained that at times they were shor breath or found they could breathe more easily the head was raised higher than usual. If such nor respiratory difficulties had not been recognised, ibarrassment would probably become evident der anæsthesia, and especially during the second ge. Tracheotomy might then be unexpectedly cessary with risks which would not otherwise have en present. Lung complications accounted for the ajority of fatalities. Oral sepsis must be vigorously rrected before operation on the throat, and though is might not be the anæsthetist's province, he was t uncommonly held largely responsible for pul-onary complications. After removal of teeth e gums must have soundly healed before the eration. Most of the subjects of serious throat erations were at or past middle age, and their ouths were seldom in really good condition. Packs aked in cocaine and adrenalin were employed to nder the mucous membrane analgesic, and they ere instrumental in lessening the amount of general næsthetic required. To make a tracheotomy pening in these cases was better than to carry ut endotracheal anæsthesia; there was always he possibility that the tube might carry infection, r at its insertion might dislodge a portion of growth nd so disseminate it in the lungs. A further reason as that a tube restricted the surgeon's field of ctivity.

For severe throat operations the anæsthetic of hoice was chloroform with oxygen. Dr. Morris aid he was aware of the existing prejudice against hloroform, and he was of course against its indis-riminate use in the wrong type of case. Mr. Wilfred Trotter had told him that during the time he had been performing these operations he had never had anxiety on account of the chloroform anæsthesia, and that was the speaker's experience over 20 years. There must be a free airway and plenty of oxygen. During the operation the patient was noticeably free from any tendency to congestion and hæmorrhage, and it was usual for him to leave the table with the coughing reflex present and the pulse little faster than at the beginning of the operation. In none of his cases had there been delayed chloroform poisoning. With modern apparatus the supply of oxygen could be kept separate from that of chloroform, and mostly no more than 3 to 4 drachms of chloroform per hour was required.

After tracheotomy the regular to and fro breathing was replaced by a different type—namely, one in which long periods of apnœa were followed by periods of dyspnœa—and this might persist throughout the operation, afterwards giving place to the normal breathing. Unless surgeon and anæsthetist were aware of this, they were apt to become alarmed and to perform artificial respiration in apnœic periods.

In the large group of cases in which the operation was away from the opening in the larynx and there was no danger of obstruction, one of the intratracheal methods was best. He preferred to apply the vapour under low pressure through a soft tube, which provided for a return airway and allowed of packing off the larynx. Passage of the tube by the nasal route had many advantages. For operations in the hypopharynx and on the cords and in which tracheotomy was necessary, he thought it might be better for the patient if the tracheotomy were always done under local anæsthesia and if time was allowed for him to accustom himself to that type of breathing, rather than for both procedures to be done under general anæsthesia at one time.

DISCUSSION.

Dr. Ll. Powell agreed with Dr. Morris's general plan, but preferred to use a bellows rather than a stream of oxygen to convey the chloroform.

Mr. Lionel Colledge agreed, as an operator in these cases, that the main principle was that there should be no respiratory obstruction. Tracheotomy was not necessary in every case. If respiratory obstruction was allowed to occur, it was usually too late to do tracheotomy, for the damage had already been done; the tracheotomy might restore the breathing, but after that the anæsthesia would not proceed quietly again, and if there was a pulmonary complication in that type of case it was not due to the anæsthetic as such but to the respiratory obstruction. He saw no object in using general anæsthesia for tracheotomy; it was much simpler and easier under a local anæsthetic, and from the beginning the anæsthetic could be administered through the tracheotomy tube. He had never seen trouble due to the use of chloroform. Delayed chloroform poisoning was relatively much more likely to develop in children and young adults. When the entire larynx had to be removed, if there was no obstruction—though often there was—it was useful at an early stage of the operation to open the cricothyroid membrane, put in a laryngotomy tube, pass the anæsthetising material through that, and remove the laryngotomy tube with the larynx. That obviated the necessity of doing a preliminary tracheotomy, and one had a clean wound, without risk of sepsis from a preliminary operation.

Dr. A. L. Flemming suggested it might be useful to add CO_2 to the mixture to overcome the apnœic phase after the performance of tracheotomy.

Mr. John Hunter endorsed all that Dr. Morris had said as to the use of chloroform in these throat cases. He found that the old men who usually required these operations took chloroform well, especially as the amount needed was materially reduced by the introduction of cocaine into the open larynx, and if morphia was used towards the completion of the operation this also lessened the required dose of chloroform. From the operative standpoint he did not see the need for the tracheotomy to be a separate preliminary procedure; it should be done at the same time as the main operation. But if obstruction existed, tracheotomy was required and the patient should be returned to bed to await the operation proper.

Sir Francis Shipway said he was glad to hear chloroform recommended. Where a tracheotomy tube was used in these cases it was impossible to give a fatal dose of chloroform. He had seen respiration arrested by a heavy dose, but though nothing was done it restarted. Nor did he think a continuous stream of oxygen constituted a danger. SECTION OF ANÆSTHETICS.

At its meeting on March 4th, with Dr. G. Ramse Phillips, the President, in the chair, this section discussed

Anæsthesia for Major Throat Operations.

Dr. C. W. Morris said these operations presented many difficulties. Respiration might be hindere by obstruction of the airway by the growth, an there was a grave threat of pulmonary complication The surgeon must be allowed the maximum freedom for his manipulations—especially in lateral pharyngo tomy. Degrees of embarrassment short of actu stridor and cyanosis must be recognised and minimised A proportion of patients would not admit they ha experienced difficulty in breathing, indeed they migh not have been aware of it; only by close questionin could it be ascertained that at times they were shor breath or found they could breathe more easily the head was raised higher than usual. If such nor respiratory difficulties had not been recognised. barrassment would probably become evident der anæsthesia. and especially during the second ge. Tracheotomy might then be unexpectedly cessary with risks which would not otherwise have en present. Lung complications accounted for the jority of fatalities. Oral sepsis must be vigorously rrected before operation on the throat, and though is might not be the anæsthetist's province. he was t uncommonly held largely responsible for pul-onary complications. After removal of teeth e gums must have soundly healed before the eration. Most of the subjects of serious throat erations were at or past middle age, and their ouths were seldom in really good condition. Packs aked in cocaine and adrenalin were employed to nder the mucous membrane analgesic, and they ere instrumental in lessening the amount of general æsthetic required. To make a tracheotomy pening in these cases was better than to carry ut endotracheal anæsthesia; there was always e possibility that the tube might carry infection. r at its insertion might dislodge a portion of growth nd so disseminate it in the lungs. A further reason as that a tube restricted the surgeon's field of ctivity.

For severe throat operations the anæsthetic of hoice was chloroform with oxygen. Dr. Morris aid he was aware of the existing prejudice against hloroform. and he was of course against its indis-riminate use in the wrong type of case. Mr. Wilfred rotter had told him that during the time he had een performing these operations he had never had nxiety on account of the chloroform anæsthesia. nd that was the speaker's experience over 20 years. here must be a free airway and plenty of oxygen. uring the operation the patient was noticeably ree from any tendency to congestion and hæmorrhage, nd it was usual for him to leave the table with he coughing reflex present and the pulse little aster than at the beginning of the operation. In one of his cases had there been delayed chloroform oisoning. With modern apparatus the supply of xygen could be kept separate from that of chloroform, nd mostly no more than 3 to 4 drachms of chloroform er hour was required.

After tracheotomy the regular to and fro breathing was replaced by a different type—namely. one n which long periods of apnœa were followed by periods of dyspnœa—and this might persist throughout the operation. afterwards giving place to the normal breathing. Unless surgeon and anæsthetist were aware of this. they were apt to become alarmed and to perform artificial respiration in apnœic periods.

In the large group of cases in which the operation was away from the opening in the larynx and there was no danger of obstruction. one of the intratracheal methods was best. He preferred to apply the vapour under low pressure through a soft tube. which provided for a return airway and allowed of packing off the larynx. Passage of the tube by the nasal route had many advantages. For operations in the hypopharynx and on the cords and in which tracheotomy was necessary. he thought it might be better for the patient if the tracheotomy were always done under local anæsthesia and if time was allowed for him to accustom himself to that type of breathing, rather than for both procedures to be done under general anæsthesia at one time.

DISCUSSION.

Dr. Ll. Powell agreed with Dr. Morris's general plan, but preferred to use a bellows rather than a stream of oxygen to convey the chloroform.

Mr. Lionel Colledge agreed. as an operator in these cases. that the main principle was that there should be no respiratory obstruction. Tracheotomy was not necessary in every case. If respiratory obstruction was allowed to occur. it was usually too late to do tracheotomy. for the damage had already been done; the tracheotomy might restore the breathing, but after that the anæsthesia would not proceed quietly again. and if there was a pulmonary complication in that type of case it was not due to the anæsthetic as such but to the respiratory obstruction. He saw no object in using general anæsthesia for tracheotomy; it was much simpler and easier under a local anæsthetic. and from the beginning the anæsthetic could be administered through the tracheotomy tube. He had never seen trouble due to the use of chloroform. Delayed chloroform poisoning was relatively much more likely to develop in children and young adults. When the entire larynx had to be removed. if there was no obstruction —though often there was—it was useful at an early stage of the operation to open the cricothyroid membrane. put in a laryngotomy tube. pass the anæsthetising material through that. and remove the laryngotomy tube with the larynx. That obviated the necessity of doing a preliminary tracheotomy. and one had a clean wound. without risk of sepsis from a preliminary operation.

Dr. A. L. Flemming suggested it might be useful to add CO_2 to the mixture to overcome the apnœic phase after the performance of tracheotomy.

Mr. John Hunter endorsed all that Dr. Morris had said as to the use of chloroform in these throat cases. He found that the old men who usually required these operations took chloroform well, especially as the amount needed was materially reduced by the introduction of cocaine into the open larynx. and if morphia was used towards the completion of the operation this also lessened the required dose of chloroform. From the operative standpoint he did not see the need for the tracheotomy to be a separate preliminary procedure; it should be done at the same time as the main operation. But if obstruction existed. tracheotomy was required and the patient should be returned to bed to await the operation proper.

Sir Francis Shipway said he was glad to hear chloroform recommended. Where a tracheotomy tube was used in these cases it was impossible to give a fatal dose of chloroform. He had seen respiration arrested by a heavy dose. but though nothing was done it restarted. Nor did he think a continuous stream of oxygen constituted a danger. Prof. Buckmaster's work showed that during chloroform anæsthesia oxygen tension was reduced by 40 per cent., so there was no danger of over-oxygenating. Oxygen was needed because during chloroform administration there was a definite anoxæmia.

Mr. T. Ritchie Rodger thought there was no sufficient reason for believing that injection of adrenalin was dangerous when chloroform was used.

Dr. J. Blomfield said that the point of importance in regard to the use of adrenalin in these cases was the difference in its action when injected and when it was applied on a swab. In Dr. Morris's paper the reference was to the use of adrenalin on swabs. These caused no trouble. and that was also the speaker's experience. The trouble which had occurred with adrenalin when chloroform was used was when it was injected.

Sir FRANCIS SHIPWAY referred to a case of chloroform anæsthesia for a mastoid operation in which adrenalin was poured into the wound to stop bleeding, and the patient died.

Dr. I. W. MAGILL said that Dr. Morris remarked that sometimes a general anæsthetic was needed for the tracheotomy but the speaker did not see why. He referred to a case of pulmonary and laryngeal tuberculosis, with much obstruction and cyanosis, in which the patient insisted on a general anæsthetic for the tracheotomy. He, Dr. Magill, decided to oxygenate the patient first, and introduced the oxygen under positive pressure through the small aperture in the larynx. That was very satisfactory to a patient who was suffering from laryngeal obstruction. His own practice was to connect up to the tracheotomy tube by a closed system, and he gave nitrous oxide and oxygen, with free medication, beforehand; chloroform could be added if necessary. In giving chloroform by the open method it was an advantage to have CO_2 also. He had been glad to hear the good word for cocaine, for its advantages were very certain. In a cocainised larynx administration of chloroform was one of the simplest and easiest forms of anæsthesia. Chloroform seemed to be the only anæsthetic a strong man with cancer of the larynx could take well, and he seemed to suffer no ill after-effects. Better results were obtained from nembutal if it were not used as a basal narcotic by itself; one should aim at a balanced anæsthesia, i.e., using some morphia and scopolamine an hour beforehand. Only a very small quantity of nembutal was then needed, and less was necessary to be eliminated from the system afterwards. Much of the restlessness of patients who had nembutal was due to their having had an overdose of it. There was no object in inducing deep sleep, it was preferable to have the patient at a stage in which he could answer questions. He had seen some successful total excisions of the larynx carried out under regional block anæsthesia; some patients did better under that than under a general anæsthetic.

Dr. HUGH PHILLIPS said that one of his practical difficulties was in the use of a lead delivery tube. This, on account of its weight, had a tendency to pull the tracheotomy tube on to one side. He had therefore had made a curved platinum tube, and attached this to a light indiarubber delivery tube. He had not found premedication necessary. The apnœic periods after carrying out tracheotomy could be quite alarming, and in these circumstances he turned on a little CO_2, with a few inhalations of ether, afterwards continuing with the chloroform. He agreed with what had been said as to the use of a local anæsthetic. He had never found any harm result from a swab of cocaine and adrenalin; it helped the anæsthesia, and the amount of chloroform required was thereby reduced.

SECTION OF THERAPEUTICS AND PHARMACOLOGY.

AT a meeting of this section on March 8th, with Dr. E. P. POULTON, the President, in the chair, a discussion on specific and non-specific

Desensitisation in Allergic Disease

was opened by Dr. G. H. ORIEL. Allergic disease and asthma, he said, were not necessarily synonymous; there was one type of asthma in which it was not possible to prove allergy. Allergy meant an altered reaction to a foreign protein, while asthma was only a symptom. Normally there was no antibody to protein in man; in sensitisation antibodies were present in the tissues but not in the blood-stream, while in immunity antibodies were present chiefly in the blood stream and to a less degree in the tissues. The ideal to be aimed at was to transform sensitisation into the normal state, but this was rarely accomplished. If a rabbit was sensitised to egg protein, egg precipitins appeared in the circulation; after a few months' rest these precipitins had disappeared but on the injection of a non-specific protein, such as T.A.B., the precipitins reappeared; in this case sensitisation had been transformed to immunity. Tuberculin, peptone, and T.A.B. had all been used in non-specific therapy.

In a case of asthma it was important to decide whether the condition was allergic or not. More than 300 proteins could be used for skin tests, which meant a tedious and exhausting process, especially as some asthmatics were positive for nearly all of them. All sensitised patients gave a positive test to human hair. Working in conjunction with Dr. Barber, he had found that a proteose was present in the urine of an allergic patient which gave a positive skin test in that patient. The proteose obtained from one asthma patient would give a positive result in another asthma patient who was sensitised to the same protein as the first. In the intervals between the attack there was little of the proteose to be found in the urine, often less than 1 per cent.; during an attack, however, it increased rapidly to about 10 per cent. and then fell again equally rapidly. This suggested that it was a break-down product; and it was important to determine whether this was so, for if the patient was sensitive to his own break-down products, treatment must be approached from that point of view.

In a passively sensitised guinea-pig an injection of proteose obtained from an allergic patient produced a typical uterine contraction. In the normal guinea-pig proteose produced only a small uterine contraction, and histamine a large one; in the sensitised guinea-pig the contractions produced by proteose and histamine were equal in size. These experiments indicated that the proteose substance was not identical with histamine. Four criteria must be fulfilled if a substance was to be accepted as the cause of asthma in a patient: (1) It should be capable of producing asthmatic attacks. (2) The Prausnitz-Küstner reaction should be positive. (3) It should be possible to use the substance to perform passive sensitisation. (4) Skin tests should be positive.

NON-SPECIFIC DESENSITISATION.

Prof. STORM VAN LEEUWEN said that after a visit and demonstration by Dr. Oriel he had prepared proteoses from 24 asthmatic patients; 11 of these had given negative skin reactions but the rest had been positive. Different persons reacted differently to the same drug, but it was only when the reaction was extreme that it was termed allergy. He found that those patients who reacted at all to Oriel's proteose also reacted very strongly to 1 in 10,000 histamine. He considered that Oriel's proteose might be responsible for some cases of allergic asthma. Those patients who reacted to human epidermis also reacted to proteose—in other words, they reacted definitely to products of the human body. The allergic patient differed from the normal person in that he was likely to become sensitised to any product capable of provoking sensitisation, provided that he came into contact with it.

t was well known that certain acute infections uld improve the condition of an asthmatic patient ; ong these were lobar pneumonia. erysipelas. amps. scarlet fever. and tonsillitis. Certain other ditions, however. had a harmful influence. and se included influenza. colds, measles. and broncho-eumonia. The problem was to decide what use ald be made of this circumstance. Theoretically. would be to the patient's advantage to induce eumonia artificially. as malaria was artificially luced in the treatment of G.P.I. As this was practicable, some less dangerous and more readily rable disease must be sought. Malaria had little ect in ameliorating asthma, and he had tried ree other diseases. The first of these was dengue. hich he had used in 12 cases. The second was little known disease described in German as *lamm* fever. and which he had translated as slime" fever, since there appeared to be no English uivalent ; this disease was found in Russia and as due to a spirochæte, related to virus disease. at completely harmless. The third disease employed was a certain strain of recurrent fever. ttempts had been made to investigate the influence f these diseases on the blood in asthmatic patients, ore especially on the eosinophil count. and on the cid-base equilibrium or pH of the blood. Most llergic patients and many asthmatics showed osinophilia. It had previously been found that tarvation, and also injections of sulphur in oil, ad an effect in reducing this eosinophilia ; as the emperature rose after a sulphur injection the eosino-hils diminished, and at the same time the amount f adrenalin necessary to keep the patient free from ttacks was much reduced. The rise of temperature ssociated with dengue was found to cause a similar reduction in the amount of adrenalin necessary to prevent attacks, but as a rule had little effect on the eosinophil count. The improvement in the asthmatic condition, however, lasted only two or three days, and infection with dengue showed no advance on the results obtained with sulphur. Slime fever gave sufficiently promising results to make further investigation desirable ; in one case the reduction in the amount of adrenalin necessary to prevent attacks had been very marked. The strain of recurrent fever used was said never to kill any patient, and the improvement produced in some cases had been remarkable. all asthmatic attacks disappearing for months. The patient's sufferings, however. were severe during the feverish attack, and some drug was essential to prevent recurrence. Salvarsan was not effective for this purpose in the artificially induced disease, and another drug not yet on the market. after being employed successfully in 45 cases, failed to prevent recurrence in the final three. Some other drug or some more reliable method must therefore be sought. It was found that these diseases had no demonstrable effect on the pH or CO_2 content of the blood. This form of therapy was chiefly effective in bronchitic asthma. and not the other forms.

Most asthmatics gave a strong positive reaction to tuberculin. and although non-specific therapy of this type was much less dangerous than induced disease, it had met with considerable resistance from the medical profession. If could not cure every patient, of course, but it was capable of producing improvement which might last for months. though it would have no effect if the patient was coming into contact with massive doses of allergin as soon as he left the clinic. Peptone injections. Prof. Leeuwen considered. were not dangerous if given intramuscularly but might cause death if given intravenously. What factor was responsible for the effects of non-specific therapy was still an open question.

CLINICAL EXPERIENCE.

Dr. **C. S. Bruce Pearson** described a positive skin test as a strong. large wheal with pseudopodia and definite persistent erythema. He quoted the results obtained in a series of cases with 0·025 c.cm. of urinary proteose in a solution of 1 in 100,000, which showed that asthmatic patients reacted much more readily and intensely than normal controls. Experiments made with solutions of 1 in 1000 had produced doubtful reactions in some of the normal control cases. There was no sharply defined limit between normal and allergic persons ; most people showed signs of allergy at some time during life, usually in the form of an attack of urticaria.

Dr. **W. P. Stamm** described a case of angio-neurotic œdema in a woman of 48. On Dec. 23rd, 1931, she had developed urticaria, which had recurred daily until Dec. 28th, when she had an acute attack of œdema of the face and lips. She was treated in the out-patient department with intramuscular injections of blood ; fish and meat were excluded from her diet. The œdema disappeared but the daily attacks of urticaria continued, and on Jan. 30th, 1932, she was admitted to the wards of Guy's Hospital. Dr. Oriel had prepared her urinary proteose from a specimen obtained during an attack. She was given a skin test dose with a dilution of 1 in 10,000, which produced a positive reaction at 4 P.M. At midnight she had a severe attack of œdema. On Jan. 15th, 0·1 c.cm. of a 1 in 1,000,000 solution of proteose was given, and again an acute attack of œdema developed at night. On Jan. 18th she was given 0·2 c.cm. of a 1 in 1,000,000 solution. and no reaction followed. From then onwards the doses were repeated at increasing intervals, and she had no further attacks of œdema or urticaria.

Dr. **John Freeman** said that he gathered that Dr. Oriel and Prof. Leeuwen regarded sensitisation to proteose as parallel to sensitisation to some product of a damaged part of the body. He had long thought that sensitiveness to iodide, for example, must be due to a product of iodide with some substance in the body rather than to iodide itself, but this was a long way from the conception that every man was sensitive to his own proteose. He was interested in the use of artificially produced disease as a method of reducing asthmatic attacks. In his experience severe colds had a similar effect, and he had always taken it to indicate that the patient had acquired immunity to some air-passage organisms to which he had previously been sensitive.

Dr. **H. W. Barber** said that he had been using proteose therapeutically for two and a half years. and had come to the conclusion that it was in a different category from non-specific desensitising agents such as T.A.B. and tuberculin. He believed that any psychological effect could be ruled out. It was necessary to find the dose which provoked no reaction and upon which the patient improved ; once found it should not be increased. In many cases the method had failed and had been abandoned. but on the whole he had had better results with it than with any other form of desensitisation which he had used.

Dr. **George Bray** suggested the possibility that reactions to human hair might be due to the presence of dandruff which contained histamine. In America diathermy had been used to produce high temperatures but as soon as the fever disappeared the asthmatic attacks returned. Was there a possibility that proteose treatment would so restore the patient that he could return to his feather bed or to dangerous articles of diet? He thought the best hope of success lay in combined treatment. Some patients were free from attacks on histamine and adrenalin.

Mr. FRANK COKE remarked on the benefit experienced by asthmatic patients during pregnancy, as well as following certain infections. He could not understand how patients could be sensitive to human hair unless it had been changed by mould.

In replying, Prof. VAN LEEUWEN said that hair and superficial layers of skin were taken from the limbs where the presence of moulds was unlikely. Histamine could be prepared from the skin, but the effects obtained with proteose were quite unlike the effects of histamine.

Dr. ORIEL, in his reply, thanked Prof. Leeuwen for the great interest he had shown in the work on urinary proteose.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this society on Feb. 4th was devoted to

Backache in Women.

Mr. HAROLD F. SEYMOUR said he thought the condition was less common than it was 20 or 30 years ago, this being due to the much healthier bringing-up of girls to-day. Whilst approving of sports and gymnastics for women, he deprecated excess and said there was a danger of producing a male type of pelvis in young women—with its obstetrical disadvantages—if sport was indulged in excessively. There never could be physical equality between the sexes. His remarks were confined to low backache in the sacral region, and he referred only briefly to gross disease such as large fibroid tumours, incarcerated ovarian cysts, salpingitis, and carcinoma. Where gross pelvic disease has been excluded, he considered there were three main causes of backache—namely, retroversion and retroflexion of the uterus, chronic cervicitis, and prolapse. In the treatment of retroversion pessaries should be used only temporarily. A Hodge's pessary would often cure a retroversion occurring after the puerperium. Persistent retroversion causing backache and other symptoms should be treated by a round-ligament shortening operation. Chronic cervicitis, he thought, was best treated by anæsthetising the patient and deeply cauterising the cervical canal after dilatation. Diathermy too was good, but he preferred the actual cautery. Bad cases not yielding to such treatment were best dealt with by amputation of the cervix. Prolapse, except in a very few cases, was due to injuries to the cervix and pelvic floor during childbirth. He thought it an obstetrical disgrace to allow small women to give birth to large children. Inductions should be done for women with only the bare normal pelvic measurements, where the child was obviously over 7 lb., and so much prolapse would be avoided. Primigravidæ over 40 should always be given the choice of a Cæsarean operation. In the treatment of prolapse pessaries should not be used except as a temporary measure, where it occurred after the puerperium and was simply due to lack of muscular tone. Persistent prolapse should be operated on, and by the vaginal route. The surgical treatment of prolapse was perhaps the most satisfactory of all operative procedures, at any rate it gave the patient complete satisfaction. She felt after the cure of her prolapse that she had returned to the time when she was a nullipara. He hoped the profession would point out the advantages of the vaginal operations for prolapse, and not let women go on wearing insanitary pessaries for years and years, when they could be made clean and well by an operation which cured their backache too.

Mr. RALPH BROOKE suggested that 80 per cent. of cases of low back pain were gynæcological in origin, and the remaining 20 per cent. orthopædic. He pointed out that in the female the posterior pelvic or sacro-iliac joints remained comparatively lax throughout life—an adaptation to function, the important female function of parturition. Sacro-iliac disorders occurred far more commonly in the female sex and at a period when the joints were most movable. Pregnancy had a great influence on the sacro-iliac diseases and injuries, owing, amongst other things, to the increased mobility of the joint at that period. At term the range of movement was increased approximately two and a half times above the maximum in the non-pregnant woman. The return of joint stability of the pelvic joints was closely related to the normal uterine involuntary changes, and uterine subinvolution was associated with a persistence of the lax conditions of these joints which was present at term. The practical application of this was seen in women who rose too early after the labour, which was complicated by uterine subinvolution. In these cases low back pain, other than uterine in origin, was a persistent symptom. Disparity between the size of the fœtal head and the maternal pelvis was another cause of disturbance in the normal anatomical and functional state of the pelvic joints, and the passage of an abnormally large head through the pelvis might lead to over-stretching of the sacro-iliac ligaments with the associated symptoms of joint strain, followed later on by those of a partial subluxation or a secondary traumatic arthritis. Partial subluxation of the joint might occur in women after pregnancy, and was usually traumatic in origin. Radiography was not of great assistance in the diagnosis of partial sacro-iliac subluxations or displacements. Arthritic changes could be demonstrated with greater certainty. Joint laxity might be treated by means of a light brace, or in less severe cases, a strong corset. Manipulation under anæsthesia was useful both as a curative measure in cases of partial subluxation, or when the pathological change was in the nature of a peri-arthritis. It was also useful in the differential diagnosis of strain and subluxation from early arthritis. In the latter a temporary increase in the amount of pain resulted from the manœuvre, but this was easily controlled by a light brace with a pelvic band and sacro-iliac pads. Operative fixation was not on the whole indicated, and should be regarded as a last resort when all other measures had failed.

Much could be done to prevent the many years of intractable backache and pain which many women suffered after pregnancy, if the period of rest in bed after childbirth was governed by the state of the pelvic joints. Persons suffering from delayed involution of the uterus required a much longer period of rest in the horizontal position. The same thing applied if the child was of large size, or the head showed marked moulding.

REVIEWS AND NOTICES OF BOOKS

Traité de technique opératoire oto-rhino-laryngologique.

By GEORGES PORTMANN, Professor in the Faculty of Medicine of Bordeaux. Paris: Masson et Cie. 1932. 2 Vols. Pp. 865. Fr. 250.

WITH the collaboration of his assistants in the Clinic at Bordeaux, Prof. Portmann has produced a valuable treatise on the operative surgery of the ear, nose, and throat. The text is laid out in tabular form arranged under the headings of indications, preparation of the patient, anæsthesia, instruments, and technique. While this makes the description of the actual operation clear and easy to follow, so condensed a method is less suitable to the discussion of the indications for an operation, the advisability of which in any individual case may be doubtful. The work begins with a description of general principles, and of the arrangement of the operating theatres, and includes an illustrated account of the theatres in Prof. Portmann's clinic. Details such as methods of illuminations are discussed, and the so-called diathermy knife is described. The method of diathermic coagulation which is in more general use in this country is not mentioned; presumably Prof. Portmann does not employ it.

The greater part of the first volume is occupied by operations on the ear, and includes a chapter on antrotomy in infants and one on the "conservative" mastoid operation; for the last named operation the indications are said to be very restricted. Curettage of the jugular bulb is advised when incision of the lateral sinus downwards fails to reach the blood current, and ligature of the jugular vein in all cases of involvement of the lateral sinus is regarded as a necessary complement to opening the sinus. The second volume is occupied by operations on the nose and throat. Prominence is naturally given to the treatment of tumours of the nasal fossæ and its accessory cavities by the transmaxillo-nasal route, designed by Prof. Moure, the author's predecessor in the Clinic at Bordeaux. Prof. Portmann describes his practice in connexion with the operative treatment of suppuration in the accessory nasal sinuses. In the operation on the maxillary antrum by the canine fossa route, he recommends a thorough curettage and the removal of the entire lining of the cavity, which is then swabbed out with 10 per cent. solution of chloride of zinc; he respects the inferior turbinal for fear of subsequent atrophic rhinitis. In operating on the frontal sinus, Prof. Portmann makes a wide removal of the anterior wall in order to treat its mucosa in the same way, and he introduces a packing of iodoform gauze from the sinus into the nose to maintain the permeability of the ostium. For tonsillectomy in children he employs the guillotine, describing the operation as that of Sluder-Ballenger: but he uses the finger, and not the eminence of the mandible, to push the tonsil through the ring, according to the method first described by Whillis and Pybus of Newcastle. For adults he uses dissection and snare, and ligatures bleeding vessels: he does not give details of how the ligatures are tied. Of the laryngeal operations, thyrotomy is described with removal of part of the thyroid ala as advocated by StClair Thomson; when a portion of the cricoid is also excised, the operation is described as a partial laryngectomy, but it is acknowledged that there is but a small difference of degree between the two procedures, and that no formal method exactly is suitable to every case. Total laryngectomy from below is the only method discussed, Glück's method of extirpation from above not being mentioned. The outstanding feature of the work is the illustrations, of which there are 467 in addition to two coloured plates. In connexion with many of the major operations photographs are shown of the surgeon's and assistant's tables, laid out with the instruments required; these are often nearly identical, for the same instruments are used in many similar operations and larger figures to show the details of the less known patterns would have been more useful. Most of the illustrations however are full-page plates depicting the various stages of operative procedures; beautifully drawn and reproduced, they give so clear a conception of the operations that further explanation is hardly required, although a short description is appended to each plate. There is no index, and a table of contents only at the end of the second volume.

Prof. Portmann has not attempted a systematic exposition of all the operations of surgery performed in this field, but has only set out to describe those practised by himself: the work will none the less be a valuable guide to those embarking on this specialty.

A Text-book of Surgical Pathology.

By CHARLES F. W. ILLINGWORTH, M.D., F.R.C.S. Edin., and BRUCE M. DICK, M.B., F.R.C.S. Edin. London: J. and A. Churchill. 1932. Pp. 677. 36s.

THE title of this work makes us regret the sonorous and dignified days of our ancestors, one of whom might have published "A Treatise on such aspects of the Science of Pathology as are of peculiar interest to those who practise the Art of Surgery." Other times, other titles, and we have no doubt that within a few months Messrs. Illingworth and Dick's book will be recognised, if not by all those who practise surgery, at least by most of those who aspire so to do, as containing an admirable presentation of that part of pathology which it is of most service for them to know.

The book differs from others of its kind in that some knowledge on the part of the reader of the basic processes of pathology is assumed, and the usual chapters on inflammation, injury and repair, gangrene, and so forth are omitted. There are, however, brief chapters on shock, burns, the pathological effects of irradiation, tuberculosis, actinomycosis, ærogenic infections, and echinococcus disease, though syphilis, streptococcal and staphylococcal, and other common infections are not specifically dealt with. And there is a chapter on the general pathology of tumours which contains far more than is usually included in work of a general character. The great bulk of the book is devoted to the lesions of the various systems which are related to surgery. The subject matter is well chosen and attractively presented, and the teaching is essentially modern. There are upwards of 300 illustrations of naked-eye and microscopic preparations including several radiograms. For the most part they are excellent but a few are below the general standard, rather because they have been ill-chosen than because they are poor reproductions. Fig. 58, for example, does not give a true impression of an osteoclastoma; nor does Fig. 165 represent an average epithelial odontome. Here and there occur a few statements which no doubt will receive further consideration in future editions—for instance, is it correct that the lungs are only rarely infected *primarily* by the *tubercle bacillus*? And is it true (p. 50) that hypernephroma occurs in fused or malformed kidneys? At any rate, this phenomenon is not referred to later in the book where these tumours are described in detail. Stronger exception might be taken to the author's conception of the tumours derived from the skin and other parts of the body covered by similar epithelium. The separation of the basal-celled carcinoma (rodent ulcer) from the squamous carcinoma by the group of glandular carcinomata (pp. 67 et seq.), the statements on p. 354 that a malignant change may supervene in a basal-celled carcinoma (rodent ulcer), and on pp. 588–89 that an epidermoid carcinoma of the pelvis of the kidney is so called because it has a certain similarity to carcinomata of the skin or mucous membranes, tend to perpetuate a state of confusion about these tumours which is unfortunate and unnecessary. The general format of the book leaves nothing to be desired, and the price is reasonable.

Ultra-violet Therapy.

A Compilation of Papers forming a Review of the Subject. By AUSTIN FURNISS, L.R.C.P., L.R.C.S., L.D.S., D.P.H. London: William Heinemann (Medical Books), Ltd. 1931. Pp. 365. 12*s.* 6*d.*

SOME of the papers collected by the author in the present volume have previously been published in medical journals. Presented now in book form they give a fairly comprehensive and up-to-date review of the whole subject of actinotherapy. The treatment of the subject is elementary throughout, but the facts are carefully presented and well documented with references to the more important work carried out by research workers in this country and abroad. Like other books intended for both doctors and laymen this volume proves at times irritating to the medical reader. The notes on general medicine and pathology do not credit the reader with even an elementary knowledge of the subject, while such brief explanatory remarks cannot be of much use to lay readers. The book forms a good introduction to the study of actinotherapy.

Röntgenuntersuchung und Strahlenbehandlung der Speiseröhre.

By Dr. JOSEF PALUGYAY, Privatdozent für medizinische Röntgenologie; Leiter der Röntgenstation der II. chirurgischen Universitätsklinik in Wien. Vienna: Julius Springer. 1931. Pp. 391. R.M.59.60.

THIS book is an illustration of a method characteristic of German scientific investigators which never fails to arouse wonder and admiration in other countries. The œsophagus is a simple organ with a single function; but on the radiology of the œsophagus alone Dr. Palugyay has compiled a work of nearly 400 pages without repetition or verbosity. He has, he explains, tried to set down the lessons he has learnt in the 12 years which he has devoted entirely to the investigation and treatment of the œsophagus in coöperation with eminent surgeons. He gives considerable space to the methodical correlation of his findings with the known physiology and pathology of the œsophagus and makes an unusually valuable contribution to its normal anatomy and physiology—a vitally important study to which too little attention has been paid. He makes no mention, in the section on the swallowing mechanism, of the negative pressure theory, but the cinematographic diagrams he reproduces seem to confirm this theory. After a long and carefully ordered study of the radiological pathology, based on an exhaustive classification, he deals fully with disease, including a special section on foreign bodies, the results of operation, and operation controlled by radiology. In the therapeutic section the use of radium and X rays singly and in combination is considered. The bibliography is, of course, comprehensive. The illustrations are as good as half-tone reproductions of radiograms can be, but much detail is necessarily lost. The line drawings, of which the book contains a considerable number, are well executed and convey much more information.

The book should be used as a work of reference by all radiologists confronted with specific problems in the investigation or treatment of the œsophagus.

Modern Methods of Feeding in Infancy and Childhood.

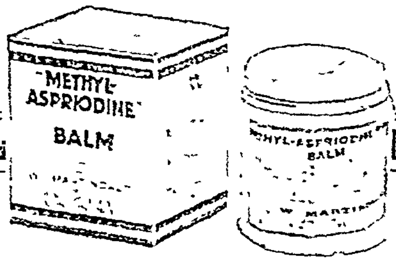
Third edition. By DONALD PATERSON, M.D., F.R.C.P., Physician for Diseases of Children, Westminster Hospital; Physician to Out-patients, Hospital for Sick Children, Great Ormond-street; and J. FOREST SMITH, F.R.C.P., Physician to Out-patients, St. Thomas's Hospital. London: Constable and Co. 1931. Pp. 170. 7*s.* 6*d.*

THIS book has already established its reputation as a guide to infant and child feeding. It is scientific in conception, practical, and easy to read. The third edition is slightly larger than its predecessors; there are few significant alterations, but the text has been rearranged and new tables are included. Some minor changes have been made in the diets recommended for older children, more stress being laid on the necessity for limiting fats. The book is among the best of its kind, and will be useful to *students as well as to practitioners.*

Infection and Resistance.

Fourth edition. By HANS ZINSSER, M.D., Professor of Bacteriology and Immunity, Medical School, Harvard University. London: Macmillan and Co., Ltd. 1931. Pp. 651. 35*s.*

IN the preface to this new edition of his popular text-book Prof. Zinsser expresses the opinion that books on immunology should either be revised every ten years or destroyed (except for a few museum copies). It is eight years since he published his third edition, and it is a matter for congratulation that he has decided in favour of rebuilding as against destruction. The book has been completely rewritten, but by careful pruning and the abandonment of worn-out theories he has made it actually a few pages shorter than before. There has been some rearrangement of the various sections. Special chapters on antigens and antibodies have been added, and hypersensitiveness is now discussed on the definite assumption that this phenomenon in man is essentially *identical with anaphylaxis in animals.* The application of the general principles of immunology to individual infectious diseases is dealt with in a separate section, which include a fair presentation of what is known about immunity to virus diseases. The literature dealing with immunology has become so vast that only those actually immersed in the subject can claim to more than a superficial acquaintance with it. *Prof. Zinsser has produced a balanced* and authoritative review which will continue to be valuable, not only to immunologists, but to workers in other branches of pathology.



"METHYL-ASPRIODINE"

(Regd. Trade Mark)

FOR

RHEUMATIC AFFECTIONS

AN EMPIRE PRODUCTION

OF GREAT VALUE TO THE INVALID

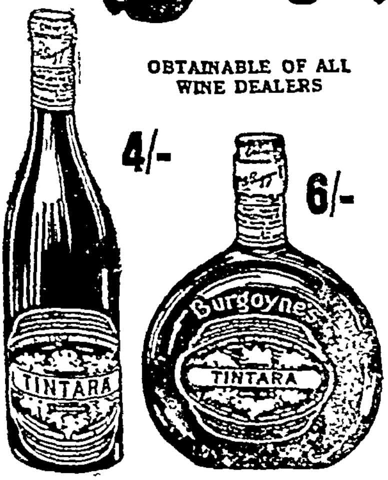
Burgoyne's

Tintara

Ferruginous

OBTAINABLE OF ALL WINE DEALERS

4/- 6/-



THIS PURE AUSTRALIAN WINE introduced in 1871, has been highly recommended by the Medical Profession in all cases where strength and nerve force have required building up. In anæmia, debility, neurasthenia, and in convalescence after any illness, this full-bodied, generous wine, palatable as well as health producing, has proved itself the finest of all natural stimulants

Sample Bottle sent free in the United Kingdom, on receipt of professional card.

ABSOLUTELY PURE

P. B. BURGOYNE & CO., Ltd.,
Burgoyne House, Dowgate Hill, London.

Announcing
the TASTELESS and INODOROUS high concentrate of vitamins A and D

The Glaxo Laboratories introduce to the medical profession their new preparation, Adexolin Liquid, which is standardised to contain the vitamins A and D present in 20 times its own volume of the finest cod-liver oil.

Adexolin Liquid, being entirely without taste or smell, can be taken and tolerated even by patients with the most delicate stomachs, by infants and adults, by the sick and the well.

One minim of Adexolin Liquid is equivalent in vitamins A and D to 20 minims of high grade cod-liver oil.

For Adults.

To serve as a general tonic and to maintain resistance against respiratory and other infections

For Infants and Children.

For promoting normal growth, dentition and ossification, and as a prophylactic against infection.

Two drops should be added to 3, 4 or more bottles a day for hand fed infants.

ADEXOLIN LIQUID

GL

In 8 c.c. phials, complete with Dropper, 2s. 6d.

Usual Professional Discount.
Dispensing sizes available.

GLAXO LABORATORIES
56, Osnaburgh Street, N.W.1

GLUCOSE-D

GL

A preparation of medicinal glucose in which is incorporated calcium glycerophosphate and vitamin D to assist a normal metabolism of calcium and phosphorus in conditions—notably acidosis, asthma, cyclical vomiting, heart disease, and fever—that may require both glucose therapy and the prolonged administration of a fat free, and thence fat-soluble-vitamin free, diet.

In 1-lb tins—1/9

Every preparation that bears the Glaxo Laboratories device has been subjected, at every stage of its manufacture, to rigorous scientific and technical control.

PRODUCTS OF THE GLAXO LABORATORIES

GL

OSTELIN EMULSION

GL

An exceptionally pleasant emulsion of Ostelin vitamin D equal to 100% high grade cod-liver oil, with 0.5% of calcium glycerophosphate.

In 8-oz. bottles ... 2/6

Colloidal Calcium with Ostelin vitamin D

GL

FOR CHILBLAINS

this preparation injected subcutaneously has been described by a School Medical Officer as a specific remedy. It is equally dependable as a prophylactic. It quickly stabilises the circulation in this, and in urticaria and other capillary disturbances.

In boxes of six 1 c.c ampoules 5/-
In 1 oz. bottles 10/-

The "G.L. Device" represents a pure, biologically high grade, and accurately standardised preparation of the Glaxo Laboratories.

LONDON: SATURDAY, MARCH 12, 1932.

THE LAW OF MEDICAL PATENTS.

THE recent annual report of the Medical Research Council recalls attention to the need of revising the law of patents of medical discovery. The Council's views had already been laid before the Departmental Committee which was appointed in 1929, with a distinguished ex-Lord Justice as chairman, to consider the amendment of British patent law. The Committee, when it reported last year, set forth the Council's recommendations but found itself unable to support them. Concerned, perhaps naturally, with commercial rights, with the standardisation of Board of Trade practice and with the general legal position, the Departmental Committee declined to contemplate any special treatment of medical patents. It was doubtless impressed also with the difficulty of reconciling conflicting interests and opinions. But, whatever the reasons for the Committee's decision on this point, we have to reckon with the fact that, in any future amendment of the law, the Board of Trade is likely to follow the advice of its Committee unless public opinion expresses itself strongly to the contrary.

British patent law took shape 300 years ago. The abuse of prerogative grants of monopoly in Elizabethan times is ancient history. The QUEEN postponed a crisis by one of the ablest speeches ever delivered to Parliament, but a recrudescence of popular grievances caused JAMES I. to bow to the storm. In 1624 the Statute of Monopolies swept away all monopolistic privileges except fourteen-year grants in favour of persons who had invented or introduced a new discovery. British patent law, concentrating upon the three elements of novelty, utility, and inventive merit, has been developed from that Statute. Though patents for projects of alchemy were not unknown, the early law scarcely contemplated application to medical discovery. In 1739, when Parliament was ready to reward JOANNA STEPHENS with £5000 "upon a proper discovery to be made by her, for the use of the public, of the medicines prepared by her for the cure of the stone," a patent could hardly have been deemed appropriate. So far as "the use of the public" is concerned, patent law came a little nearer to our present problem when in 1859 an Act enabled improvements in instruments or munitions of war to be assigned by the inventor, "for valuable consideration or without," to the Secretary of State for War. The next development for our purpose is as recent as 1919. The war had revealed a shortage of medicine and drugs often the subject of patent rights in this country. Section 38 A (2), then inserted in the principal Act, enabled the comptroller of patents to grant licences where patents existed in respect of food and medicine, thus restricting the effect of a monopoly. In settling the terms of the licences or the amount of the royalties, he was to "have regard to the desirability of making the food or medicine available to the public at the lowest possible price consistent with giving to the inventor due reward for the research leading to the invention." This formula bred dissatisfaction because it recognised and encouraged the derivation of private gain from the patenting of medical inventions. The medical profession has its ethical principles and is unaccustomed to the idea that a practitioner should profiteer in respect of a discovery in the medical field. There are no notices in that field warning trespassers that they will be prosecuted. Our research workers have their traditions of publicity and coöperation. But voluntary abstention from patenting has the disadvantage that the results of British medical research may be exploited by others, especially foreigners, who are not amenable to those traditions. And our chemical manufacturers must have some protection. To meet these difficulties a scheme was proposed for the compulsory dedication, in the public interest and under State administration, of all patents for inventions subserving medical purposes. The Departmental Committee weighed the opinions for and against this proposal. The medical profession proved not to be unanimous. Workers in applied pathology and preventive medicine suggested that it was ethically no worse to reward research which reduced human suffering than to give a surgeon or physician a fee for his services. There were manufacturing chemists who declared that medical inventions were already hampered by Section 38 A, and that further restriction would discourage research by commercial firms or, alternatively, would encourage secrecy as a method of monopoly. In the end the Departmental Committee decided against compulsory dedication on the ground that it would operate adversely to the British fine chemical industry and discriminate unfairly against our research workers.

The Medical Research Council's proposal is more sweeping. Aiming higher than individuals' royalties and aware of the traditional disinterestedness of professional ideals, the Council wishes Britain to abolish altogether (as certain other countries have already done) the right of patenting medical discoveries. Obviously, commercial interests will be prejudiced by such abolition unless all the nations agree. Until international agreement is attained, the Council looks not unfavourably upon the dedication scheme; but the legislative amendment which the Council advocates is "the total abolition of the right of patenting in the medical field or some nearly equivalent restriction of that right." The arguments of the Medical Research Council may be briefly repeated. Patent rights exist in order to stimulate discovery. They are not required in the medical field because the worker abjures recourse to patents; he has

proportions, and that, in particular, the formation of leucocidin is a consistent feature of pathogenic strains. GENGOU lays stress on the fact that it is the filtrate which produces these changes; the dead staphylococcus is harmless when washed, and cannot evoke antibodies of this type. He has further shown that the organism when lysed by bacteriophage is innocuous, and does not produce antibodies of antitoxic value. By using various combinations of organism, lysed organism, and filtrates he failed to protect animals against living staphylococci. It is impossible, however, to neglect the action of these nocuous substances, on whose distinction from each other PANTON and VALENTINE insist, in the production of infection, or to refuse the possible aid of antisera. It is known that the antistreptococcal sera will fail to protect rabbits against eventual death from living cultures; but they will delay it for many weeks. Antisera might thus be expected, in human staphylococcal infections, to convert a lethal infection to a sublethal one; and, above all, to offer a chance of localisation and abscess formation, which is the best prognostic sign in septicæmia. And this analysis of pathogenicity will probably serve in the selection of strains for immunisation of animals, to procure sera with optimum and selective antibody characteristics.

One point, however, is often overlooked in the consideration of pathogenicity of organisms. It is certainly not outside the bounds of possibility that recovery from infection by an organism may be associated with a mutation of that organism, associated with diminished virulence. Such mutations may be imposed by an immune state in the infected individual; and mutation can in fact be imposed in vitro by immune sera. In any epidemic infection, towards the end of the epidemic, cases tend to be less severe. Epidemics do not end with the infection of all susceptible individuals; it is more probable that the virus is attenuated. It is possible that in the future therapy on this basis may be developed; the logical line of advance at present surely lies in the analysis of pathogenic action, and the utilisation of all established specific antibodies with which research workers may provide us. And for their concrete services we can forgive them a great many syllables.

PSYCHALGIA.

QUOTING from lectures given by Sir BENJAMIN BRODIE in 1836, PRATT, GOLDEN, and ROSENTHAL[1] remark that they contain much concerning the neuroses that is not yet generally known by medical teachers and writers. Although BRODIE laid stress on the frequency of pains of hysterical origin, yet nearly all English and American physicians since his time have mistaken for organic disease those cases presenting severe localised pains of psychical nature. The usual false diagnoses are neuralgia, neuritis, or myalgia, though sacro-iliac disease, appendicitis, gall-bladder disease, peptic ulcer, colitis, irritable colon, ovarian neuralgia, and hypertrophic arthritis have played their part. Even in pre-anæsthetic days the patients willingly underwent the horrors of operation, and this fact Dr. PRATT and his colleagues take as evidence that the pain is not only real but very severe—an explanation probably too simple for the psychopathologist, who would attempt to find deeper and unconscious motives at work. After a reference to CHARCOT'S caustic description of surgical intervention in such cases, they note that the development of technique since his day has increased needless operations on the victims of neurotic pain to an extent that no one can measure. A method of demonstrating the psychic nature of these pains was suggested by the work of SOMA WEISS and D. DAVIS on the effect of injecting percaine in the localised area of skin to which pain in visceral disease was referred. This as a rule abolished the pain, but only while the anæsthesia lasted. Used in cases of psychalgia, the percaine gave complete relief in 45 cases, or 83 per cent.; when a sham injection was given in a second group the results were even better, pain being abolished in 93 per cent. The duration of relief followed no rule, but varied from 3 hours to 18 months or longer. Five cases are described in detail, cure being claimed in one patient who had been subjected to 14 operations, including the removal of the appendix and both ovaries and the fixation of a floating kidney. Whether similar results would be obtained by others is uncertain, for the removal of hysterical symptoms by suggestion is haphazard therapy, but the experimenters have proved their point that numerous cases of psychalgia exist unrecognised and that hysteria, as SYDENHAM said, "most frequently occurs of all chronical diseases." They show how this prevalence has been emphasised again and again by various writers (eight are specifically cited) and we venture to doubt whether the failure to recognise it or to make a correct diagnosis in specific cases depends upon lack of knowledge. A recent correspondence in our columns[2] dealt with another aspect of the subject and stressed the need for the consideration of psychological factors by surgeons and gynæcologists; but SYDENHAM, BRODIE, and the others, reached correct diagnoses by methods that are surely still available. The cause of our failures appears to be not ignorance but a mental attitude that has persisted through the years in spite of protests. There must be a fundamental defect in a professional training that makes us ignore the nature of many of the common disorders for which people seek our help, and the remedy seems to lie in inculcating a different attitude rather than in adding to our knowledge.

Manson House, the new headquarters of the Royal Society of Tropical Medicine and Hygiene, will be opened by the Prince of Wales at 5.30 P.M. next Thursday, St. Patrick's Day. The address is 26, Portland-place, London, W.1, and admission to the ceremony will be by ticket only.

always pooled his knowledge gladly and the incentives are not financial. Patent law, it is added, was not meant for discoveries in biology or medicine; biological discovery is often so difficult to define precisely for the purposes of patent practice that there is risk of staking out claims wide enough to limit other explorers unduly. There is a danger too that the patenting of a medical discovery for personal profit will lead to a scramble for proprietary rights in further applications of that discovery where inventive merit may have had no influence or opportunity. The Council has had its own experience of patent rights. It does not desire them for itself. It accepted the British rights in the preparation of insulin in order to secure standard strength and quality and to prevent the marketing of inferior preparations. As soon as the Therapeutic Substances Act was passed in 1925 these objects were secured under Government control and thenceforward the Council made no further use of its patent. A second instance, the Steenbock case, provides the council with an illustration of its argument. With the aid of public money British research produced vitamin D in highly potent form by the ultraviolet irradiation of ergosterol; when our manufacturers were given the chance to apply the discovery, a British patent granted to Prof. STEENBOCK, of Wisconsin, was found to be an obstacle. The Council has published its reasons for saying that this patent is founded on the earlier and unpatented discoveries of various workers, and notably of British workers, and for holding it unreasonable that he should have the power to control the results of so much previous and subsequent work. We have also, it seems, to reckon with patent rights held for profit by foreign universities; the restrictive result is the same whether the proprietor is an individual or a corporate body.

To these arguments, as already stated, the Departmental Committee replies in effect that no case is made out for special treatment of medical patents—the medical field is like any other field and the disadvantages of patents of monopoly are more than offset by increased stimulation of industry and invention. As for the ethical considerations the Committee's attitude is that, if the medical profession has a special code, well and good—let it continue to enforce it. "But we feel strongly that the code should not operate to discourage that full coöperation between laboratory and clinical investigations which is essential to progress in this important field of human welfare." The findings of the Departmental Committee, we repeat, are likely to shape the policy of the Board of Trade; but the commercial aspects of our problem ought not to engross attention in its treatment by Parliament. The Ministry of Health knows that other interests are at stake. The Therapeutic Substances Act, with its Advisory Committee and its statutory machinery for licensing and testing, seems to offer a possible solution. The scheme for compulsory dedication of patents would be strengthened if production under a dedicated patent were brought within the Act. Nothing, however, is likely to be done unless some proposal can be put forward with the reasonable hope of agreement.

STAPHYLOCOCCAL IMMUNITY.

IT has been stated by a medical pessimist, strangely enough a surgeon, that a scientific fact is something determined by experiment which remains true for not less than two or more than five years. It is true enough that science has an uncomfortable habit of development—that the examination howlers of to-day may be the prize-man's answers of to-morrow is in some cases hardly an exaggeration. A new discovery, such as that of the rôle of the staphylococcus in infection, at first seems adequate in itself. But analysis shows the pathogenicity to be complex: and the discovery of each separate pathogenic weapon of the organism only emphasises that other and more important weapons are undiscovered. Immunology to-day has become an awe-inspiring subject. The tendency of bacteria to vary, to produce a large variety of distinct changes on tissues, to evoke a number of specific antibodies, and yet to maintain a fundamentally constant personality, is highly confusing. In time, we may be sure, conceptions will become simplified. All toxins have as much in common as in contrast; antibodies as a class have their similarities. Perhaps in the event the pure chemist, with his analysis of the behaviour of colloids, will reduce all our toxins, hæmolysins, agglutinins, and the rest to simple terms of colloidal structure and aggregation. Meanwhile, we must be content to suppose the existence of distinct causal entities from the study of distinct phenomena, and to leave to the future the unifying conceptions.

Recent work on the staphylococcus emphasises the analytical tendency in immunology. Two facts are quite obvious. The living staphylococcus can kill an animal; and from the staphylococcus substances capable of killing and otherwise damaging animals can be separated. But, although this nocuous power of filtrates has been analysed, and although antibodies can be prepared, it is not possible to protect animals against the living organism, so as to prevent eventual death, by means of antisera. Since, however, it is possible to recover from staphylococcal infections, it follows that immunity is not solely, or even mainly, dependent on the antibodies which have been discovered, and that pathogenicity of the organism is based on elements other than those determined by the most elaborate analysis. The paper by Dr. P. N. PANTON and Dr. F. C. O. VALENTINE in our last issue, and the work of Dr. O. GENGOU,[1] bring the process of analysis one step further. Filtrates of staphylococci will produce necrosis of skin, lysis of red cells, and destruction of leucocytes, and will kill a rabbit. Complete neutralisation of these phenomena can be procured by antisera. It is shown that different strains of staphylococci produce these nocuous substances in different pared for the Metropolitan Asylums Board, now merged into the London County Council, an exhaustive report upon the factors which appeared to be operative in the production of return cases of scarlet fever and diphtheria, and upon the efficacy or otherwise of hospital administrative methods designed to limit their occurrence. This report and a subsequent one to the same authority by F. M. Turner are classical. Although Klein in the 'eighties had described a "Streptococcus scarlatinæ," his work was either not accepted or ignored. Thus Cameron and Turner had not the advantage of bacteriological aid in their investigation of the infecting case of scarlet fever. With the acceptance of the hæmolytic streptococcus as the causal organism of the disease, it is natural that the possibilities of bacteriological control should be explored. Amongst others, U. Friedemann and H. Deicher[1] in Germany and M. B. Kirkbride, M. W. Wheeler, and C. D. West[2] in the United States have already made important contributions to the subject. A more recent investigation is that of J. E. Gordon,[3] of Detroit, who compares the value of bacteriological control in the uncomplicated and complicated case of scarlet fever. He finds that swabbing before discharge to determine the presence of the hæmolytic streptococcus in the throat of the uncomplicated case is not justified by results, as judged by the proportion of infecting cases after release. The uncomplicated case of scarlet fever may be discharged with equal safety after 28 days' isolation with or without swabbing. The infecting case rate was not greater for those proved to be carriers than for those shown to be bacteriologically free. In this connexion it is significant to note that W. Gunn and F. Griffith[4] reported that of 100 consecutive cases of scarlet fever, 49 harboured the hæmolytic streptococcus in the throat and six in the nose at the time of discharge from hospital, and that, so far as could be ascertained, not one of these 55 carriers acted as infecting cases. Kirkbride, Wheeler, and West found that only two out of 34 patients (6 per cent.) who were known to be carriers gave rise to return cases. Friedemann and Deicher[5] record that 100 per cent. of a series of cases were tonsillar carriers of the hæmolytic streptococcus after six weeks' detention in hospital. They seek to explain the low infectivity of the scarlet fever carrier on the grounds that the hæmolytic streptococcus loses virulence and toxicity in convalescence.

---

[1] Ann. de l'Inst. Pasteur, February, 1932, p. 135.

In the case of scarlet fever complicated by rhinitis, cervical adenitis, or otitis media terminal swabbing is an undoubted advantage. Gordon found that the bacteriological control of these cases materially reduced the period of isolation, and that the infecting case rate in this group was reduced from 11·9 per cent. amongst those not swabbed before release to 5·5 per cent. when two consecutive negative cultures were demanded. Rhinitis is of outstanding importance as a cause of infectivity: in Cameron's series 50 per cent. of the infecting cases had rhinitis at some time or other; in Gordon's series, although rhinitis and sinusitis occurred in only 14 per cent. of his cases as a whole, the condition was present in 40 per cent. of those which acted as infecting cases. Gordon distinguishes between the infectivity of purulent and catarrhal rhinitis. The hæmolytic streptococcus is present in abundance in the discharge associated with the former condition but is rarely recoverable in the catarrhal form. Cameron made the same distinction based upon observation alone. Cameron was of opinion also that otorrhœa, unless a morbid condition of the nose coexisted, was seldom associated with the production of return cases. The Ministry of Health Report on Scarlet Fever issued in 1927 also expressed doubts as to the infectivity of scarlatinal otorrhœa. Gordon believes that "the patient with suppurative otitis media is scarcely more infectious than the patient released after simple scarlet fever." In some fever hospitals in this country bacteriological control of the scarlet fever patient with complications of a suppurative nature is already being carried out with a view to reducing both the length of stay and the incidence of return cases. Routine swabbing of the uncomplicated case before discharge is clearly not called for. Gordon does not state whether his cases were treated with scarlet fever antitoxin. There is little doubt that antitoxic treatment by lessening the incidence of complications generally also tends to reduce the return case rate.

MORTALITY AMONG SANATORIUM PATIENTS AFTER DISCHARGE.

AN interesting supplement to the studies of Dr. Noel Bardswell and others in connexion with the ultimate fate of sanatorium patients is to be found in a monograph[1] by Dr. F. Lange-Nielsen, published under the auspices of the Norske Videnskaps Akademi and with the financial support of the Nansen Fund. An English summary at the end, and English captions to the tables, do much to illuminate the text, which is in Norwegian. The study does not make cheerful reading. The patients discharged from the public sanatorium of Grefsen in the period 1910–1916 numbered 887 men and 1065 women, belonging chiefly to the working-classes. When the investigation of the subsequent fate of these patients was completed at the end of 1921, only 26 could not be traced. In 1924 Dr. Sofie Tillisch, who had worked as her husband's assistant at the sanatorium, produced a preliminary account of this material which has now been rearranged with the aid of statisticians. While the actual number of deaths was 1056, the number of deaths among the same number in the general population would have been only 88·1. In other words, the mortality among these ex-sanatorium patients was twelve times greater than the normal, and their expectation of life was no better than that of Norwegian males at the age of 80. Yet the average age of the patients on discharge from the sanatorium was only about 28 years. It should, however, be noted that approximately half the patients belonged to the third Gerhardt-Turban stage of the disease, and that the mortality after discharge among the first-stage patients compared with that of the general population was only as 2·7 to 1. From this figure of 2·7, the mortality rose to 7·5 for second-stage patients, and to 27·5 for third-stage patients. In his discussion of his findings Lange-Nielsen draws attention to the remarkably low mortality among first-stage patients during the first year after discharge, and he is inclined to credit sanatorium treatment with a goodly share of this achievement. But in the absence of a similar body of tuberculous patients not given sanatorium treatment, he has been unable to make that comparison which, more than any criterion, would have enabled him to form an

ANNOTATIONS

VENTILATION OF ROADWAY TUNNELS.

NAVIGABLE rivers are commercial assets to the districts through which they flow, but they offer barriers to communication between places situated on opposite banks. High-level bridges are of limited application, swing bridges are not very convenient either to vehicular traffic or navigation, subfluvial tunnels have therefore been adopted both here and in America as the best solution of the problem. Two early tunnels of this kind were pushed under the Thames. one at Blackwall in 1897, the other at Rotherhithe in 1908—both at a time when the horse was the principal means of haulage and seemed likely to remain so. The rapid development of internal-combustion engines and steam lorries has complicated the problem of ventilation which was simple enough when only the products of complete combustion. such as occurs in the animal system, were concerned. Natural ventilation has been found inadequate in removing to a safe degree the carbon monoxide. sulphur gases. and free carbon with tarry matter which result from the less complete combustion of fuel in mechanically propelled vehicles. In road tunnels of this kind the need for easy gradients has led to making long slopes on either bank with air shafts at intervals, utilising the caissons used during boring. which convert the tunnel from a simple U tube into one pierced in several places. These communications with the open air serve as inlets or outlets. according to the incidence of traffic, the varying air pressures and differences of temperature within and without the tunnel. Sections of tunnel between them may at times be filled with air which is, if not actually stagnant, at most oscillating to and fro without being drawn out of the tunnel. The products of imperfect combustion are at such times evident. not merely to the chemist, but by their effects on the well-being of those using the tunnel, more particularly those working in it. A further serious source of danger is the fog produced under these circumstances, which adds greatly to the difficulties of driving. In the event of a stoppage, due to a breakdown in the tunnel or to a traffic block at one end, the atmosphere becomes much worse, and serious malaise may be experienced. Tunnels which have been constructed since the advent of the mechanically propelled vehicle have been designed in the hope of overcoming these troubles. The experience of the London Underground railways with one-way tunnels has shown one direction in which improvements can be made. The construction of the roadway as an inner shell. surrounded by outlet and inlet channels for artificial ventilation by fan-driven air currents. ensures safe use even under the congested conditions of modern traffic. But it is one thing to project and another effectively to achieve, and one of the latest tunnels, that under the Mersey at Liverpool. has. almost on the eve of the opening ceremony, been found to have inadequate provision for ventilation.

In the Blackwall and Rotherhithe tunnels much improvement has been effected by the introduction of air at appropriate places. A scheme has been evolved by the engineering staff of the London County Council in collaboration with the chemical branch. and the work is described by Mr. C. J. Regan in a recent report [1] to the chief medical officer. In examining the effect of the progressive installation of currents of fresh air by means of fans, which was started at Blackwall in 1922 and at Rotherhithe two years later, Mr. Regan and his colleagues, on the advice of Mr. J. H. Coste, the L.C.C. chemist, have used Gautier's iodine pentoxide method, as modified by Teague, for determining the carbon monoxide, liquid air employed to remove the traces of hydrocarbon gases—pentane and hexane—which would interfere with the accuracy of the process. Humidity measured by a recording hair hygrometer, supplemented by a standard Assman wet and dry bulb instrument. Owens's air filter was used for measuring soot, and sulphur gases were determined by the Government chemist using a process based on G. H. Bailey's hydrogen peroxide method of oxidation of sulphur dioxide. The question of lead fumes from ethyl-petrol was left in abeyance. Consideration was given to the results of physiological experiments on the effect of carbon monoxide in varying concentration on human beings. In estimating a figure for the maximum allowable concentration of carbon monoxide in a tunnel in which men may be employed on maintenance work for several hours at a stretch, attention was paid to the conclusion of Sayers that long exposure to low concentrations of CO causes far more tissue damage than slight exposure to high concentrations; it was deemed advisable that the CO content should not be allowed to exceed 20 parts per 100,000. The New York State Bridge and Tunnel Commission, it is recalled. first adopted a standard of 40 parts per 100,000, stiffening it later to 25 parts per 100,000. It may surprise many people to learn that the air of busy town streets may contain an appreciable amount of carbon monoxide; Bloomfield and Isbell took 141 samples at peak traffic in 14 towns of the United States, and found average carbon monoxide content of 8 parts per 100,000. Connolly and others examined 690 street air samples in Chicago, of which 85 per cent. gave 5 parts per 100,000 carbon monoxide or less. The average figures varied from 5·3 per 100,000 in busy parts to 1·5 per 100,000 in suburban districts. In central London during the winter Mr. Regan has found an average of 3·4 parts of CO per 100,000. In the tunnels. however, the smoke or fog may become the limiting factor for comfort as soon as carbon monoxide, and the maximum allowable quantity of suspended matter was put at shade 6 of fog samples, being 1·92 mg. of black suspended matter per cubic metre. The highest daily average percentage of humidity of the tunnel air was 88 at Blackwall and 84 at Rotherhithe, and at no time was 100 per cent. reached at either place, clearly indicating that the fogs in the tunnels were not water vapour fogs. Mr. Regan's paper should be read by authorities contemplating the construction of underground garages or car parks, which may become death-traps for those who have to remain there for hours at a stretch, unless care is taken to ensure, under all conditions, an effective removal of products of combustion.

RETURN CASES OF SCARLET FEVER.

WHATEVER the precautions adopted, from 2 to 4 per cent. of scarlet fever patients released from isolation initiate further cases of the disease within, as a rule, a short period of rejoining the family circle. Nearly 30 years ago A. G. R. Cameron pre-research, a definite, rigid procedure was developed: a procedure which in our hands resuscitated 82 per cent. of our 52 cats, and 52 per cent. of our 29 dogs." The order of treatment which was found most reliable in resuscitating animals killed by ether, chloroform, or electric shock is summarised as follows: "Place the animal immediately in shock position. Begin artificial respiration by manual compression of thorax. . . . Apply abdominal binder. Expose and cannulize femoral vein, and inject epinephrin into femoral vein and wash it to the heart by a small amount of glucose." There is no mention in the experiments of stimulation of the heart by puncture of an auricle, a method that was shown in Shipway's paper to be of much value in human resuscitation, and, on the other hand, injection of a drug (epinephrin) is rated at a value which human experience hitherto has rarely corroborated. This very likely depends on the fact that the effective method of washing the drug to the heart which is readily carried out in the laboratory is less likely to be easily applicable in the circumstance of a human patient collapsed on an operating table. Neither the drugs, nor the instruments, nor a skilled person free to avail himself of them may be present under ordinary conditions. The "shock position," by which we imagine is meant a position in which the head is made the lowest part of the patient, seems to be the primary need for the collapsed subject, whether animal or human, whatever subsequent measures are also needed.

DANGEROUS DRUGS.

THE results of the Bangkok Conference on opium smoking in the Far East have engaged the attention of the recent session of the Council of the League of Nations. The Opium Advisory Committee was requested to prepare a form of annual report to be made by those governments in whose territories opium smoking is sanctioned, such report is to include particulars of measures taken to discourage the practice, and to cure opium addicts, and statistics are to be furnished giving the consumption per head of "prepared" opium by smokers of different nationalities, and current prices paid for licit traffic therein. Mr. Yen, the Chinese representative, explained that his Government took no part in the Bangkok conference which was convened under Article 12 of the Geneva agreement of 1925, to which China was not a signatory. The reason for such abstention was that the agreement gave no definite assurance that the legalised traffic in "prepared" opium would, within a reasonable period, be brought to an end, as contemplated by The Hague opium Convention of 1912. "China," Mr. Yen said, "remained as heretofore bound only by The Hague Convention, of which she was a signatory, and not by agreements, final acts, declarations or other decisions of the Bangkok Conference." He added that China associated herself with the American observer at the Bangkok Conference in willingness to aid all practicable measures towards suppression of the vice of opium smoking while refusing concurrence with those governments which approved a monopoly system and refrained from attempting prohibition. The report of the Egyptian Government's Narcotics Bureau for 1931 indicates the activity displayed under the direction of Russell Pasha as well as the vast extent of the illicit traffic discovered by the Egyptian police. In 1931, 4327 traffickers and 2882 addicts were arrested, and more than 14,000 kilos of contraband narcotics were seized at the customs in addition to 11,649 kilos confiscated inside the country. On Feb. 17th a new Dangerous Drugs Bill was introduced in the House of Lords to amend the previous Acts of 1920 to 1925 in order to give effect to the provisions of the Geneva Convention (No. 2) of 1931 and thereby supplement The Hague Convention of 1912 and the Geneva Convention (No. 1) of 1925. Numerous additions are made to the preparations of opium and coca alkaloids to which the Dangerous Drugs Act 1920 to 1932 will apply in the event of the Bill becoming law.

EXFOLIATION OF THE LENS CAPSULE.

IT has recently been established that chronic glaucoma in old people is sometimes caused by a degenerative change primarily affecting the anterior capsule of the crystalline lens. Vogt, of Zurich, first drew attention to the condition in 1925 as the result of his observations with the then recently introduced slit-lamp. Other observers, both in his own clinic and elsewhere, followed him, and now Dr. Mohamed Sobhy Bey, of the Cairo Ophthalmological School, publishes a paper [1] on the subject. It appears that in certain cases in old people fluffy whity-blue masses are observed adherent to the pupillary border of the iris or loose in the anterior chamber. These were connected by Vogt with certain changes on the anterior surface of the lens only visible under strong illumination. The changes consist in a faintly opaque central disc and a more peripheral ring of finely granular opacity not continuous with the aforementioned disc but connected with it by faint radial lines. Nine out of the 12 cases observed by Vogt were glaucomatous, and he put forward the hypothesis on clinical grounds that the observed deposits were not inflammatory but degenerated portions of the lens capsule which when they are present in the anterior chamber are apt to produce glaucoma by collecting in the angle and blocking it in the same way that the inflammatory deposits of cyclitis do. During the last six years a certain number of cases showing Vogt's syndrome have been published both from his own clinic and by observers elsewhere, but the subject is somewhat new to English readers. Dr. Sobhy, who was himself a worker in Vogt's clinic at Zurich, has collected over 20 cases seen either by himself or by others of the Egyptian ophthalmic school. He publishes pathological sections of two eyes excised for glaucoma which show the conditions to be just as Vogt described them. It is noteworthy that in one of them although the eye was excised for glaucoma the optic disc showed no typical glaucoma cup. Exfoliation of the anterior capsule appears to be not very rare in old people—17 per 1000 of those over 60, according to the figures of the Zurich Eye Clinic. Of these a considerable number, though by no means all, are affected with glaucoma. It must therefore be recognised as a true occasional factor in causing that disease.

CINEMA WELFARE.

THE national conference that was held at the University of Birmingham on Feb. 27th, under the chairmanship of Sir Charles Grant Robertson, passed a resolution calling on the Home Secretary for a comprehensive inquiry into the arrangements by which films are licensed for public exhibition. In a brief report in our issue of last week (p. 547) the support given to this resolution by Lady Barrett approximately accurate estimate of the value of sanatorium treatment. This study is not a little impaired and rendered to a certain extent academic by the fact that, since the period under review, the treatment patients receive in sanatoriums has undergone far-reaching changes, and sanatorium physicians have learned much before adopting the treatment which is more or less orthodox to-day. Auto-inoculation by exercise under the elusive guidance of the opsonic index has largely been replaced by immobilisation of the lungs by a variety of means and the patient has a much greater chance of benefiting from treatment in the best-managed sanatoriums than he had in the period with which Lange-Nielsen deals.

VITAMIN STANDARDISATION: STANDARD CURVES OF RESPONSE.

THE establishment of international standard materials for the vitamins A, D, B_1, and C, which was so successfully carried out last summer, has received notice in our columns. A further step forward is shown in Dr. J. H. Burn's sixth annual report of the Pharmacological Laboratories which we have just received from the Pharmaceutical Society of Great Britain. Vitamin estimations can only be carried out by means of experiments with animals, and anyone familiar with the wide variation in response of individual animals in tests of this type will understand how difficult it must be to establish any sort of standard of behaviour. Yet this has now been achieved for more than one vitamin. If sufficiently large groups of animals are used, the average values of their reponses to graded doses of the given vitamin tend to arrange themselves into a regular series; accordingly, when dose and response [illegible] d a curve results which, with [illegible] may be taken to represent a standard curve of response to known amounts of standard vitamin material, against which the vitamin value of unknown substances may be tested. The nutrition department of the Pharmacological Laboratories, of which Miss K. H. Coward, D.Sc., is in charge, has been in the van of this interesting piece of progress, and has constructed standard curves for vitamin A, for vitamin D, and for vitamin C. In the first instance it is the growth response of test animals which has been standardised: in the case of vitamin D it is a particular reaction of the bone by calcification; and in the case of the antiscorbutic vitamin it is a histological change in the teeth of guinea-pigs which has provided the response. Other workers have used the X ray appearance of the bone as the particular form of response selected for standardisation in the case of vitamin D and curves have been constructed both in continental laboratories and in that of the Medical Research Institute at Hampstead. The development is certainly important in bringing vitamins into line with drugs which have to be tested biologically, and further important progress in the same direction is to be anticipated.

PLEURISY AMONG HOSPITAL NURSES.

THE incidence of pleurisy with effusion and erythema nodosum among the nurses in training at an important hospital in one of our dominions caused some anxiety last year. The nurses do a term of duty at a sanatorium, and in the course of their work are also attached to a tuberculosis balcony at the main hospital. The actual percentage affected can hardly be ascertained, since the precise number of women at risk is not available; but it can be estimated approximately from the fact that about 45 probationers enter the hospital and about 25 complete their training, in each year. Among the probationers (about 180 in number) who entered over a period of four years there occurred six cases of pleurisy with effusion. Five out of the six had nursed consumptive patients, and four reported sick between three and 12 months after exposure (one record is incomplete). Most of the girls were country-born, but had attended school in towns of some size. In all cases lymphocytes predominated in the pleural fluid, and in one case tubercle bacilli were found; all underwent sanatorium treatment for some months, with apparently satisfactory results. The incidence was thus something over 3 per cent. among all entering probationers. Records of the incidence of erythema nodosum extend over five years, and thus apply to about 225 women: 10 cases were observed (about 4½ per cent.); 7 of the probationers had completed their tuberculosis nursing, and 6 of these became affected while actually nursing tuberculous patients, sometimes after short periods of exposure—i.e., 13, 12, 10, 8, 7, and 3 weeks. A ward-maid from the sanatorium was admitted to the hospital with the same complaint. In all cases complete recovery occurred and the subsequent health has been good. Whether the figures are so far in excess of the expected rates for pleurisy with effusion and for erythema nodosum that they must be regarded as significant, in the absence of a control group in the same area, is not certain. If the cases of pleurisy with effusion are all presumed to be cases of respiratory tuberculosis, and if they represent the entire incidence of such tuberculosis in the population of nurses, this incidence may not be abnormally high. But that all the cases of respiratory tuberculosis in that population took the form of pleurisy with effusion seems unlikely, though we have no information on this point. A good deal more information than has been supplied to us is required if the incidence is to be regarded as more than suggestive. The exposure to risk in the dominion from which this report comes may differ greatly from that in this country. We trust that a fuller report on the circumstances will be published. The figures are to some extent comparable with those given by Heimbeck in Norway (quoted by Topley and Wilson[1]) who investigated 397 probationer nurses, all of whom were tested with tuberculin. Of these 43, or just over 10 per cent., suffered from tuberculosis (including erythema nodosum) within three and a half years. About half the girls gave positive and the rest negative tuberculin reactions on joining, and it is noteworthy that 40 out of the 43 cases of infection were among the negative reactors.

THE ORGANISATION OF RESUSCITATION MEASURES.

AN article under the above title[2] comes as an interesting complement to the paper read at the last meeting of the British Association by Sir Francis Shipway, an abstract of which appeared in our own columns.[3] The American contribution relates laboratory experiences only, but its authors seek to draw useful conclusions for application in the case of human beings. They say that "since clinical application was the goal of the

SPECIAL ARTICLES

THE COASTAL HEALTH RESORT:

ITS VALUE AND DEVELOPMENT.

At Hastings last week-end the sun shone brightly at the foundation of the first sectional branch of the new British Health Resorts Association. The founders took the opportunity to discuss the present and future use of the British coast in its relation to health and recreation, and a great variety of opinions found expression.

Medical Aspects.

Dr. W. G. **Willoughby** (medical officer of health for Eastbourne and President of the British Medical Association) took the chair at the first meeting. It was true, he said, that one and a half to two hours more sunshine could be enjoyed daily on the Riviera, but the climate of the southern English resorts was much more equable, and to invalids this was very often an important advantage. Like many subsequent speakers, he felt that far too little systematic work had been done on the reactions of the body to a sojourn at the seaside, and that *too little information* was available to profession and public on the particular uses of particular places in this country.

Dr. E. P. **Poulton** (physician to Guy's Hospital) pointed out that the air in different places had the same composition. But just as patients on hospital balconies ate 50–100 per cent. more than those in the wards, so people at the seaside received a metabolic stimulus. It was hard to say how far the increase of resistance of children at a place like Hayling Island was due to sunshine, and how far it was due to cooling of the skin. It had been noted that at the seaside the temperature of the skin tended to fall, whereas the temperature of the feet rose—a sign of improvement in circulation. The children in question had come from crowded cities and he could not say that the same thing did not happen when they were sent to the countryside inland. At a place like Hastings, however, visitors might have the benefit of sea-bathing, not only in summer, but also, in the warm sea-water swimming-bath, throughout the winter.

RESPIRATORY DISEASE.

Dr. R. A. **Young** (physician to Middlesex Hospital) regretted that even the medical profession knew so little about climatology. It was strange, he said, that only during the last century people came to understand the health-giving properties of change to mountains, moors, and coasts—previously condemned as bleak and dour and deserted. Now, however, these properties were appreciated in almost every country, especially perhaps on the Continent in Holland and France. The marine resorts could, he thought, play a big part in preventing chronicity of catarrhal and chest affections (to which his remarks were confined). After illness of the "influenzal" group a few days' residence at the seaside was capable of restoring vigour and activity, and perhaps even more important was its value in clearing up residual cough. Cough was a symptom apt to recur year after year in winter, and its summer intermission often grew shorter and shorter until chronic bronchitis was continuous throughout the seasons. The sequence could sometimes be broken by spending two or three winters at the coast, preferably arriving at a time when it was still possible to spend much of the day out of doors. Emphysema was also helped by staying at the seaside, but asthma presented a more individual and local problem which needed local investigation. It was often said that the tuberculous should not go to the sea, and it was true perhaps that they should not live at sea-level. But many of the most efficient sanatoriums were on the coast, and great benefit could often be derived at the seaside by patients who would not enter sanatoriums or had been discharged from them, and also by those with tuberculous pleurisy for whom institutional life was often unnecessary. More accommodation should be available for such cases, and to this end the unreasonable fear of contracting infection from the tuberculous should be broken down. Much remained to be learnt about the complex effects of climate, said Dr. Young in conclusion, and there was room for experiment at coastal resorts with such methods as inhalation therapy and compressed air-baths like the one at Brompton Hospital which had proved useful in emphysema and other conditions, yet remained unique, he believed, in England. Doctors at coastal resorts must pool their experience and tell their colleagues elsewhere what patients to send and what patients *not* to send. To send unsuitable cases was bad for the patient, bad for the doctor sending them, and bad for the health resort.

CHILDREN.

Dr. **Leonard Findlay** (physician to the East London Hospital for Children) said that his investigations with the late Prof. Noël Paton had demonstrated the immense importance of environment in the development of children, and also the superiority of country over town. To some extent the difference was due to better maternal care in rural districts, but he had no doubt that fresh air and sunlight played the most important part. These were found at their best on the coast, where the air came in fresh and uncontaminated from the sea. Here the body was readily trained to react to varying conditions, while (as for the mind) there was no place where a child could be so easily entertained—on a playground thoroughly cleansed twice daily. There were opportunities, moreover, for the best form of physical exercise. This was always a bit of a problem in childhood, because its value depended on the vigour with which it was performed, and there must therefore be interest in the movements themselves or the result of their performance. Swimming was ideal, and it should be possible, with warmed and sheltered water, to provide for it throughout the year. For the convalescent, with his lessened power of heat production, there must be sunny playgrounds guarded from the wind—and where better than on the south coast, at the very doors of the largest section of the population of these islands? A stay at the seaside should benefit children convalescing from pulmonary infections and nephritis, and also many with active disease when this was not associated with too great prostration. With tuberculosis of bones or joints, or rheumatism, as good results could be obtained in this country as anywhere—provided sufficient time was allowed for treatment. The doctor must demand one, two, or three years, for often the degree of success varied with the length of treatment. Usually special accommodation was required, but in the less severe cases much could be done with spinal carriages. Room and protection should be found for these on the sea-front, and easy paths should be available for them. The fear of infection of other children was

Dr. W. A. Potts, and other medical speakers was duly noted. The conference was convened by the Birmingham Cinema Inquiry Committee, which came into being about April, 1930, owing to dissatisfaction (to use a mild expression) with the prevalent type of film, and particularly with the baneful effect of that type on children and adolescents. The promoters of the Birmingham movement maintain that this great instrument which modern science has given to the world can be, indeed is bound to be, a tremendous and inexhaustible source of recreation and education, and for that reason they are determined to persist in their endeavour until its abuses and dangers have been extirpated. Members of the committee have made it part of their work to investigate the influence of the cinema upon children themselves. The picture-houses which the children chiefly frequent were attended regularly for a period of nine months by investigators who sat with the children, talked with them, and watched closely the effects of films upon them. Their results were embodied in a report of great interest issued early last summer.[1] We understand that the general feeling at the conference was that similar inquiries should be undertaken in other centres outside Birmingham. Dame Ethel Shakespear suggested that the conference should appoint seven of its members to act as a standing committee with powers to coöpt others, but a subsequent proposal made by the National Council for Mental Hygiene appeared to be more acceptable to the delegates present. This proposal was that each centre should create its own local committee, and that a national committee should be formed representative of the several local committees. If the proposal matures we should like these bodies to be known as Cinema Welfare Committees, with a constructive rather than a merely destructive outlook.

THE ROYAL SOCIETY

THIS year, for the first time, the Council of the Royal Society has been charged to recommend 17 instead of 15 candidates for election; the great increase in the range of scientific effort throughout the Empire more than justifies the innovation. Among those recommended our readers would be especially gratified to observe the following names: Dr. J. B. Orr, the director of the Rowett Institute, Aberdeen, who has carried out important researches on protein metabolism, on respiration, and on the influence of vitamins and mineral constituents upon normal metabolism and disease; Dr. Warrington Yorke, professor of tropical medicine at the University of Liverpool, is distinguished for his researches on trypanosomiasis and its transmission, and on hæmoglobinuria; Dr. Davidson Black, professor of anatomy at the Union Medical College, Peking, is distinguished for his researches in comparative neurology; Dr. F. R. Miller, professor of physiology at the University of Western Ontario, has also devoted himself particularly to the study of the nervous system; Prof. F. C. Bartlett holds the chair of experimental psychology at Cambridge, and his publications embody much original research in this comparatively new field; and Mr. J. B. S. Haldane, Sir William Dunn reader in biochemistry at Cambridge, has contributed to our knowledge of acid-base equilibrium in man, and his work has had important bearings on therapeutics. Among others less directly concerned with medicine we have to welcome the names of Mr. F. E. Fritsch, D.Sc., professor of botany at the University of London, who is the principal British authority on the fresh-water algæ; Prof. J. A. Gray, who is the Chown research professor of physics at Queen's University, Kingston, Ontario, who has made important advances in the study of radioactivity; Mr. R. D. Hartree, Ph.D., who holds the chair of applied mathematics in the University of Manchester; Mr. Karl Jordan, Ph.D., director of the Zoological Museum at Tring, whose work is mainly on the taxonomy and anatomy of insects; Mr. J. L. Simonsen, D.Sc., who holds the chair of chemistry in the University College of North Wales; Mr. Thomas Smith, head of the optics section of the National Physical Laboratory; Prof. H. W. Turnbull (St. Andrews), who is distinguished in mathematical research; Mr. F. W. Carter, Sc.D., who has materially advanced the foundations of electrical engineering; Mr. W. G. Fearnsides, Sorby professor of geology at the University of Sheffield; Sir Basil Mott, President of the Institution of Civil Engineers; and Mr H. S. Taylor, D.Sc., professor of physical chemistry Princeton University, U.S.A.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDE FEB. 27TH, 1932.

Notifications.—The following cases of infectio disease were notified during the week:—Small-po 73 (last week 72); scarlet fever, 1429; diphtheri 908; enteric fever, 35; pneumonia, 2158; puerper fever, 39; puerperal pyrexia, 121; cerebro-spin fever, 62; acute poliomyelitis, 7; acute poli encephalitis, 1; encephalitis lethargica, 17; continu fever, 1; dysentery, 44; ophthalmia neonatorum, No case of cholera, plague, or typhus fever w notified during the week.

The number of cases in the Infectious Hospitals of t London County Council on March 1st–2nd was as follow Small-pox, 116 under treatment, 2 under observation (l week 129 and 10 respectively); scarlet fever, 127 diphtheria, 1544; enteric fever, 13; measles, 15 [illegible] puerperal fever, 21 (plus 10 babie [illegible] 3; "ot [illegible] there were babies (plus 10 mothers) with ophthalmia neonatorum

Deaths.—In 117 great towns, including Lond there was no death from small-pox or enteric fev 64 (20) from measles, 9 (2) from scarlet fever, 48 from whooping-cough, 44 (8) from diphtheria, 53 (from diarrhœa and enteritis under two years, a 324 (47) from influenza. The figures in parenthe are those for London itself.

The reported deaths from influenza have not risen furt Of the great towns Sheffield stands highest with 18 deat followed by Leicester with 15, Bristol with 12, Birmingh and Great Yarmouth each with 11, Bradford and Nor ampton each with 10. The total deaths for the year fr influenza so far amount to 2656, compared with 2625 the corresponding period of 1931. Manchester ag reported 6 deaths from measles, Dagenham 4. Whoopi cough claimed 8 victims in Liverpool, 7 in Birmingh Liverpool reported 8 deaths from diphtheria, Salford 3

The number of stillbirths notified during the we was 307 (corresponding to a rate of 45 per 1 births), including 54 in London.

CHRISTIE HOSPITAL, MANCHESTER.—The funds the Christie Hospital (cancer pavilion an home), Manches have been depleted by £45,000, the cost of the and the erection of the new hospital at Withingt By the time the buildings are completed not more t £10,000 of endowment will remain; the investment inc will thus be reduced from over £6000 to barely £20 Since the new hospital will have 101 beds, more than tr the present accommodation, a much larger income be needed, and an appeal is being made for at l £150,000.

---

[1] See THE LANCET, 1931, i., 1409.

mmission's recommendation that there should be eparate licence for hotels and restaurants as opposed public-houses.

Mr. **Clough Williams-Ellis**, F.R.I.B.A., gave an static account of the ideal seaside pavilion and the eal wet day to be spent in it. Combining the ntheon of the gods of gaiety with what the Russians ould call a "home of pleasure and culture," the ilding offered all possible amenities amiably eltered under one hospitable roof, and its master ceremonies was an ex-ambassador who had lost is job through devoting his despatches to reports galas and fêtes. From the planetarium to the nnicipal creche Mr. Williams-Ellis outdistanced e Arabian Nights, and he was certainly right in ying that the first town to put up his pavilion would ave many visitors.

Mr. **Marshall Sisson**, A.R.I.B.A., showed pictures f what had already been attempted in this direction, hiefly abroad, and also showed his own design for a easide recreational centre.

The British Health Resorts Association.

Dr. **Willoughby** said that no existing organisation epresented the medical point of view. The spas ad set a good example in collating and systematising he information at their disposal. There was no wish to decry the value of foreign resorts, of which all were aware, but it was probable that the value of our own watering-places had hitherto been understated.

Lord **Meston** said that at the present time there was one export for which there was little or no justification—namely, the export of our own people and money. Was it true, he asked, that other countries had better facilities for cultivating health? This was the question to which the Association set itself to give a negative reply.

Colonel **Elliot** said that the movement had for the first time the unanimous backing of the medical profession, and this could only be retained if it was free from commercialism. He did not know where the movement would lead, but the motto all through would be "Britain first." For the present the British Health Resorts Association was concentrating on the coasts, "but if the spas think we can help them there is nothing we should like better."

Dr. **Fortescue Fox** (chairman of the medical advisory committee) expressed his interest from the purely medical point of view. No organisation had addressed itself in a serious and orderly way to the science of health resorts, and he had reluctantly come to the conclusion that they had gone as far as they could on an individual basis. The problem was a national one to be tackled in a coöperative spirit, and the help of any other organisation would be welcomed. In such a body efficiency must ultimately depend on the peripheral nervous system—the sense-organs and end-organs—and he appealed for the assistance of medical men at the coast.

Resolutions were passed providing for the establishment of a south-eastern region (southern section) branch of the Association, and a local council for Hastings, both medical and lay, was nominated as one of the constituent parts.

The Conference.

Throughout the week-end the conference received the greatest possible hospitality from the local municipalities, hotels, hospitals, and medical men. The Mayor of Hastings welcomed the members at a banquet in the Queen's Hotel on Friday night, and threw open the resources of the town to the visitors. On Sunday three of the leading hotels of Eastbourne entertained 120 guests at luncheon at the Grand Hotel, where speeches were made, among others, by the Mayor (Councillor Lachlan MacLachlan) the medical officer of health (Dr. Willoughby), and Prof. J. D. Stanley, of Birmingham. Here, too, Sir StClair Thomson gave the second of two speeches which will long be remembered by those who heard them. Finally, at Bexhill, on Sunday afternoon, the Mayor (Mrs. C. I. Meads) gave a tea-party in the Granville Hotel, and gracefully provided a christening cake for the Association.

THE LANCET COMMISSION ON NURSING.

(Concluded from p. 534.)

Collected Recommendations.

The recommendations contained in the Final Report,[1] which were signed by all the Commissioners, are as follows:

THE GAP.

I. Conditions of service in the nursing profession should be altered in such a way as to attract a far larger proportion of those girls who in any case will stay at school till they are 18.

II. An extensive trial should be made of combined scholarship and maintenance schemes throughout the country for girls of 16 upwards, with possible extension of such schemes to girls of 14. (See para. 71.) These girls should be chosen, not solely on examination results, but taking into consideration other factors, such as the record and interests of the girl, and probable suitability for nursing. These schemes would be rendered more effective by periodical visits of parties of school-girls to hospitals in their neighbourhood. Such visits would awaken their interest and encourage them to apply, where necessary, for maintenance grants, which could be allocated in accordance with the principles set out in proposition (2) in para. 93.

III. The curriculum in these scholarship courses should be general rather than special until the girl has reached 16 or 17, and after 17 anatomy, physiology, and hygiene could be introduced in direct preparation for the first part of a divided Preliminary State examination.

IV. Encouragement should be given to girls who have left school and are occupied in shops or offices during the day to study anatomy, physiology, and hygiene in evening classes in polytechnics, technical schools, and evening institutes, and to take the proposed Part I. of the Preliminary State examination. The same classes could be attended by girls over 17 who are working in various departments of hospitals or in convalescent homes, and possibly by first year nurses at Affiliated, Associated, or Reciprocal hospitals.

COST OF TRAINING.

V. Hospitals should recognise that the nurses are paying indirectly, if not directly, for their training, and that the onus rests on the hospitals to provide good facilities for such training, including expert instruction during hours on duty. To this end a practically baseless, and the public must learn that there was no danger in using a health resort both for the sick and healthy.

---

[1] The Report may be obtained from The Lancet Office, 7, Adam-street, Adelphi, W.C.2, for 2s. 6d., post free 2s. 9d., or through any bookseller.

NERVOUS DISORDER.

Dr. **Wilfred Harris** (physician for nervous diseases, St. Mary's Hospital) said that victims of worry were usually best treated in an environment totally different from that of their homes. Some should be sent far away, but the large majority could be looked after most satisfactorily in this country. The south coast was a valuable terrain for these cases. An important advantage was the possibility of easy coöperation with local hospitals and medical men, which avoided the cross-purposes and difficulties that often arose abroad. A further advantage was that the journey was short, without risk of infection in Purple Train or Diamond Aeroplane. But if the best use was to be made of the opportunities a good deal of organisation was necessary. Much had been done for instance at Hastings, but he would like to see further development of the medical baths, together with provision of a solarium and manipulative treatment for wasted muscles. Among the therapeutic agents which might be useful in nervous disorder Dr. Harris included ice-rinks, winter-gardens, dancing-floors, golf-courses, and "mild gambling." He thought it would be hard for English resorts to compete with those abroad unless the present interferences with personal liberty were somewhat relaxed.

Dr. Harris disagreed with Dr. Poulton's statement that air everywhere had the same composition, and Dr. Poulton qualified it by explaining that while the proportion of oxygen was everywhere about 20·93 per cent., what was more important was its partial pressure, which varied with moisture, barometric pressure, and temperature.

LOCAL OBSERVATIONS.

Dr. G. R. **Bruce** (M.O.H. for Hastings) said that each year 7000 or 8000 people passed through the 25 or 30 convalescent homes in the town. Experience at the two tuberculosis hospitals, Eversfield and Fairlight, showed that early tubercle did extremely well in the locality, while cases in private nursing homes and rooms could have excellent medical care. Among conditions successfully treated at Hastings he mentioned especially catarrhal infections, asthma, nervous debility and dyspepsia, and post-operative convalescence.. Hitherto the benefits of convalescent homes and the like had been mainly offered to the working classes, but the British Health Resorts Association wanted to extend them to the middle and professional classes by making available in hotels and lodging houses the accommodation and diets suited to invalids.

Dr. **Hill Joseph** said he had been 34 years at Bexhill, and could recommend it for cases of insomnia, Graves's disease, surgical tuberculosis, very early phthisis, chronic bronchitis, anæmia, and cardiac disease when not too advanced. But it was no use sending a person to the seaside unless he could stand some exposure to wind.

Dr. **Percy Lewis**, of Folkestone, said that all the towns in the area had the advantage of shelter from east and north winds. He pleaded for closer study of physiological reactions at the seaside on the lines of Häberlin's investigations at Wyk-auf-Föhr.[1] Just as a plant might wither on sudden removal from the conservatory, so delicate children might easily be the worse for sudden exposure at the seaside, with more food, excitement, and exercise, and a longer day. Acclimatisation at Folkestone took about a month, but at the schools it was found that during the first year the children always relapsed in the holidays. It was best to arrive at the seaside school at the beginning of the summer term.

Dr. J. R. **Dingley** (medical superintendent of Robertsbridge Sanatorium) pointed out that some patients required stimulation and others shelter. Children suffering from undernourishment and over-clothing usually flourished when their clothes were removed; on the other hand, elderly people with bronchitis and asthma also did very well in the locality if they took reasonable precautions. This was essential, for worse than to send unsuitable cases to the seaside was to send them to a doctor who would not give the necessary supervision. In chronic tuberculosis the place of treatment was not so important as the discipline.

What the Visitor Wants.

"You can't get people to go to places where they won't be amused and interested," said Lieut.-Colonel R. H. **Elliot**, F.R.C.S. (chairman of the executive committee of the Association). "They won't go; they won't stay; and if they do stay they'll never come back." They did not ask for haunts of vice or for gambling-halls, but they did want reasonable amusement. It was a great pity that the health resorts should not encourage their visitors' interest in the archæology and bird life around them—to give but two examples.

Lord **Meston** (chairman of council of the Association), who presided over the second session of the conference, spoke of the elaborate organisation which looked after patients going to foreign resorts; they were cared for from the moment they started, and were made to feel that someone was in charge of them. In this country, however, "having made up your mind that you're going to any particular watering-place, you've got to fight your way to it, fight your way into it, and fight your way *to a cure*."

Sir **StClair Thomson** touched on the same point in his speech at the banquet given by the town of Hastings on Friday night. "Non curatur quis curat," he said; you cannot be cured if you are worrying about your health. The basis of French civilisation was good food and good manners, and even in small French hotels one would often find central heating and hot water in every room. The English coast needed to follow this example so that the visitor could always be warm and comfortable and well fed.

Mr. R. C. **Vaughan**, describing hotels as "the heart of every holiday," said that in England they were rapidly improving. At a census as *long ago* as April, 1930, there were over 500 country hotels with hot and cold water in every bedroom. The real trouble in maintaining good accommodation at the seaside was the shortness of the season, and he hoped the Association would prove that nearly every coastal town was healthy nearly all the year. Municipalities forced up hotel prices by levying heavy rates, and at Bath the hotel managers complained that visitors were discouraged by high medical fees! As for Dora, would it not be possible to have a lighter touch on our sunny seashores? "Can't we allow them to be just a little gay?"

Mr. L. A. **de L. Meredith**, speaking at the banquet, said that the Travel Association, of which he is secretary, would urge fulfilment of the Licensing

---

[1] Brit. Med. Jour., 1931, ii., 331, 348; see THE LANCET, 1931, ii., 37.

xxxv. Off-duty time should be arranged in advance,) that the probationer knows *at least* a week before-and between what hours she will be free on a given ay.

xxxvi. A probationer on day duty should be free o go out between the time she comes off duty and edtime without special permission.

xxxvii. Some measure of telephone facilities should e provided, and where possible reception rooms for uests should be available in the Nurses' Home.

xxxviii. Attendance at meals adjacent to off-duty ime should not be compulsory.

xxxix. Not less than three weeks' annual holiday hould be allowed.

Trained Nurses.

l. Sisters and staff nurses should be given improved onditions of service, on lines suggested in paras. 68 and 269.

li. Where the provision of fresh accommodation for nurses is under consideration, the possibility of giving some of the nurses the alternative of living out by the offer of non-resident allowances should be explored.

lii. Efforts should be made to attract girls with administrative ability into the profession.

liii. Posts as staff nurse should be reserved for fully trained nurses.

PROFESSIONAL EDUCATION.

xl. The *Preliminary State examination* of the General Nursing Council should be divided into two parts: Part I.—Anatomy, Physiology, and Hygiene; and Part II.—Theory and Practice of Nursing.

xli. Part I. should as a rule be taken before, but not more than two years before the nurse enters the wards. If a hospital wishes to admit a girl who has not taken Part I., or has failed in Part I., this should not be forbidden, provided that she is not admitted to lectures in medicine and surgery, or to Part II., before she has passed Part I. A girl who had taken Part I. more than two years before she entered hospital might be required to take it again.

xlii. The General Nursing Council should recognise as centres where the lectures for Part I. can be given, any institutions, including secondary schools, where adequate arrangements have been made to give this tuition, and in which the tuition provided is not inferior to that provided at hospitals approved as Affiliated, Associated, or Reciprocal hospitals. The lectures should be given either by a medical man or woman, or by one who holds a university degree in these subjects, or a certificate from one of certain specified physical training colleges.

xliii. The General Nursing Council should exempt from any subject in Part I. anyone who holds a university degree which includes that subject, or has passed an advanced examination in it—e.g., an Intermediate examination in science.

xliv. Questions in the *Final State examinations* for all parts of the register should be confined to nursing treatment, and should not involve systematic medicine, surgery, gynæcology, or psychiatry.

xlv. Hospital authorities should assume responsibility for releasing a nurse from duty at least on the day before, as well as on the day of, her final written and oral examinations.

xlvi. Sister tutors should be provided in the proportion of not less than 1 to every 60 nurses in training.

xlvii. Sister tutors should not be required to undertake any duties other than those connected with education.

RECOGNITION OF PREVIOUS TRAINING.

xlviii. The General Nursing Council should empower all hospitals approved as complete training schools giving a three years' course to make an allowance for time spent in any other approved training school, provided satisfactory evidence of such service is produced.

DOMESTIC WORK IN HOSPITALS.

xlix. A redistribution between nurses and ward-maids of the domestic work in the wards of hospitals is urgently required. We recommend the provision of sufficient ward-maids to relieve nurses of domestic duties not directly concerned with the patient.

STAFFING OF NON-APPROVED HOSPITALS.

liv. Hospitals which are not approved by the General Nursing Council should not seek to enlist probationers for training, but should be staffed by trained nurses and domestic workers.

TUBERCULOSIS HOSPITALS.

lv. In the Supplementary part of the register containing the names of nurses trained in the nursing of persons suffering from infectious diseases, a special section should be included in which should be placed the names of nurses trained in the nursing of patients suffering from tuberculosis.

lvi. Higher pay, greater amenities, and long holidays should be offered in connexion with work in sanatoriums.

MENTAL HOSPITALS.

lvii. The filling of ward sisters' and higher posts by nurses who have had a general as well as a mental hospital training is desirable. Greater facilities for fully trained mental nurses to take a two years' course in general hospitals are urgently required.

lviii. The provision of teaching, and accommodation for study, should be adequate; and probationers should be encouraged to undergo progressive training. Hospitals which have sought and obtained approval by the General Nursing Council as training schools should provide teaching for the State examinations.

lix. Special care should be taken that young, inexperienced probationers do not begin their work in wards where the patients are likely to be abusive, noisy, or violent.

lx. The stretch of work during which no meal is provided should never be as long as 7 hours.

lxi. Advertisements should show clearly what is the net salary offered at the time of appointment, and nurses in hospital should be furnished on pay-days with a statement showing the gross amount due to them and the deductions which have been made.

The Conclusion to the Report.

In concluding this survey it will be well to repeat what was said in opening it—that it has been restricted to a search for causes remediable within the limits of the present system of hospital staffing without fundamental change. Within these limits it has revealed many differences in the existing practice of hospitals. It has revealed inequalities of pay and conditions where duties and responsibilities are not dissimilar; restrictions that are hard to explain except as survivals which have only to be pointed out to be removed; an apparent indifference in some cases to the changes that have taken place in the opportunities outside nursing and the expectations of educated women; and a very general failure to coördinate entry to the nursing profession with the later stages of school life. On the other hand, it has revealed much fruitful experiment; many hospitals ward sister who has to train successive batches of students should be given extra remuneration, and some relief from other duties, for teaching in the wards. (See para. 132.)

VI. Neither a maximum nor a minimum standard of payment to probationers is recommended in the present condition of shortage. The policy most likely to attract suitable candidates is that of offering low salaries to probationers and increasing the remuneration of the trained staff.

VII. As an experiment, certain hospitals which are known to give good training should advertise for probationers without offering any remuneration, but offering six weeks' holiday a year and two short periods of study leave (one week each) during the period of training. Scholarships could be given to ensure the supply of sufficient candidates until the scheme became well known.

VIII. The professional education of nurses should be encouraged by the provision of funds expressly allocated for the purpose—e.g., endowments and State subsidies.

SALARIES OF TRAINED NURSES IN HOSPITALS.

IX. *Staff Nurses.*—While the minimum scale of salary set out by the College of Nursing is adequate at important hospitals, considering that the post is a "learning" one, payment on this scale is unlikely to attract staff nurses to small, outlying, or special hospitals. We advise these hospitals to offer initial salaries between £65 and £80, varying with the experience and amenities provided.

X. *Ward Sisters.*—The minimum salary in hospitals not approved as training schools should be £80, rising to £120. The minimum salary for ward sisters in hospitals approved as partial training schools should be £90, rising to £150. The minimum salary for ward sisters in hospitals approved as complete training schools should be £100, rising after eight years to £160.

If the existing system is adjusted on these lines, we suggest that £10 of the ward sister's salary in approved training schools should be regarded as a fee for teaching.

XI. *Non-Resident Posts.*—The inclusive salary and emoluments offered to non-resident sisters should be of not less value than £250 a year—College of Nursing minimum scale for non-resident posts.

XII. *Higher Posts.*—We recommend the universal adoption of the College of Nursing scale of minimum salaries for posts higher than that of ward sister. This scale has already been adopted by many hospital authorities. In the higher administrative posts the responsibilities of the officer increase with the size of the hospital and the allocation of minimum salaries on the basis of the number of occupied beds is equitable.

SALARIES OF DISTRICT NURSES.

XIII. The College of Nursing minimum scale for resident district nurses (£85 to £120) should be adopted by District Nursing Associations, and if an *all-inclusive salary is offered, it should be a minimum* of £230, rising to £250 after a short term of service.

SUPERANNUATION.

XIV. All voluntary hospitals, institutions, and associations employing nurses should participate in the Federated Superannuation Scheme for Nurses and Hospital Officers.

XV. Early steps should be taken to secure the interchangeability of pension rights among employees of all Local Authorities, whether they have adopted the Act of 1922 or have a Local Act superannuation scheme, and to make provision for superannuation obligatory on Local Authorities.

XVI. Section 8 of the Local Government and Other Officers' Superannuation Act, 1922, should be extended to apply to nurses migrating between employment under *Local Authorities adopting* the Act, and employment under any institution

in the Federated Superann

and Hospital Officers, and to nurses leaving hospital to undertake private nursing.

HOURS OF DUTY.

Day Duty.

XVII. The span of work should not exceed 13 hours.

XVIII. If on one, or at most two days a week the span should be extended, it should not exceed 14½ hours, and the extra time should be compensated for by extra hours off duty.

XIX. At least 1½ hours should be allowed for meals during the span, of which 40 minutes should be allocated to midday dinner.

XX. Not less than three clear hours off duty, independent of meal times, should be allowed during the span every day.

XXI. One free day each week should be allowed.

Night Duty.

XXII. The hours of night duty should not exceed 57 in any week.

XXIII. The span of night duty should not exceed 11 hours, and should be less if possible.

XXIV. If on three nights a week at most the span should be extended to 12 hours, this should be compensated for by a shorter span on the remaining nights.

XXV. If the span is 11 hours or more, 1½ hours in all should be allowed off duty for meals and rest.

XXVI. One free night should be provided every week irrespective of three-monthly breaks.

XXVII. No nurse, except a night sister engaged as a permanent officer, should be on night duty for more than three months in any year.

CONDITIONS OF ADMISSION AND SERVICE.

Probationers.

XXVIII. The forms of application sent to candidates and the Hospital Rules supplied to probationers should be revised and modernised where necessary.

XXIX. A clause requiring long notice of withdrawal should be substituted for the threat of fines or other penalties for breach of contract.

XXX. The matron should have power to suspend, but not to dismiss, a probationer pending investigation by a committee of the Board of Management.

XXXI. A separate bedroom should be provided for each nurse; the number of bathrooms should be adequate; and the common rooms and dining-room should be airy and well appointed.

XXXII. A varied and well-cooked diet should be provided. In large institutions an expert in domestic science should be appointed to undertake the housekeeping and supervise the cooking.

XXXIII. The supervision exercised over a probationer in the Nurses' Home should be relaxed; for example, she should not have to retire to bed before 10.30 P.M., or to put out lights half an hour after retirement. The privacy of her bedroom should be respected. Permission to smoke should not be unduly restricted.

XXXIV. The Nurses' Home should be run on informal lines as a hostel under a Warden.

PANEL AND CONTRACT PRACTICE

Emergency Treatment.

WHAT is an emergency? This is a question which panel committees are always discussing when considering claims from practitioners under the emergency treatment scheme with its scale of fees. A patient suddenly falls ill, has a severe pain, or meets with an accident. He (or generally a relative) sends for his panel doctor, who may not happen to be at home. The messenger then, without saying who the patient is or even where he lives, generally flies off to another doctor who attends, gives the necessary treatment, and afterwards claims for remuneration. The insurance committee passes on the claim to the panel committee for consideration and decision. The doctor who has attended also sends a notice to the patient's own doctor, notifying him that he is claiming a fee under the emergency scheme according to the prescribed scale. The panel committee obtains statements of the case from both doctors before arriving at a decision. If the doctor who treated the patient (we may call him the emergency doctor) says the case was urgent, and his description confirms this—e.g., a hæmorrhage—the decision is a simple matter when it comes before the panel service subcommittee of the panel committee. The emergency doctor obtains his fee because the panel doctor was not available, and the money for its payment is deducted from the panel doctor's next cheque.

The first complication occurs when the emergency happens a long way from the patient's own doctor, so that no message can be sent to him, and if it were sent he would be too far away to get there in time to attend without ill-effects to the patient through waiting. Here the panel committee will order the emergency doctor to be paid according to scale, not however from the patient's own doctor's remuneration, but from the general fund, out of which all panel doctors in the area are paid. The next complication is where the emergency occurs in the area of the patient's own doctor, to whom however no message has been sent, treatment being demanded (and obtained) from a nearer doctor. Here the question of whether it is an emergency becomes important. If in the opinion of the committee the case is of such urgency—e.g., hæmorrhage from a cut, or a stroke—that the patient's own doctor could probably not have been obtained without the patient suffering harm through waiting, the emergency doctor will be paid from the general practitioner fund. But if the case was not thought to be of that degree of urgency, no claim at all will be allowed by the panel committee; the emergency doctor has then to obtain payment for his attendance from the insured person. A borderline case would be a speck of grit in the eye. Difficulty arises in this type of case where a practitioner, called by nervous relatives for something thought to be an emergency, to which he is bound under the regulations to attend, has to report to the panel committee that when he arrived there was no emergency, with the result that his claim for a fee is disallowed. He has then to claim from the insured person, often with little probability of being paid at all.

An aggrieved practitioner has the right of appeal to the Minister from the decision of the panel committee. The payment for emergency services is laid down in a scale of fees in the local distribution scheme. One item in the London area is a fee of one guinea for the treatment of a fracture. In a case which came recently before the panel committee a doctor claimed this fee for treating a fractured clavicle. There had been an accident, a pain, a lump in the region of the clavicle. The doctor examined the case, diagnosed a fracture, and treated it as such. He sent in his emergency claim for one guinea. In such cases the emergency doctor can only claim for one attendance; the patient, after the emergency has been treated, returns to his own panel doctor. In this case the patient called to see his own doctor the following day, when examination revealed subluxation of the acromio-clavicular joint without evidence of fracture. The point here that arose was that the doctor diagnosed the case as a fracture and treated it as such, and he therefore claimed a guinea fee. But X ray examination showed no fracture, and under the distribution scheme a guinea could not be paid to a case that was not a fracture, no matter what it was thought to be at the time. After discussion the panel committee decided to allow an emergency fee of 5s. for attendance at the surgery, but disallowed the fracture claim.

It should be added that there are several areas where no emergency fees are allowed. Each doctor does the emergency work that comes his way without payment, and in return has his own patients attended to in an emergency without charge.

Disciplinary Action: the Ministry of Health and the General Medical Council.

Last November a letter was sent by the General Medical Council to the Ministry of Health suggesting that it would be helpful if the Council could be officially informed of cases in which the Minister of Health had taken disciplinary action in regard to practitioners whose names appear upon the panel. A reply, dated Feb. 17th, 1932, was received from the Minister to the following effect:—

> "I am directed by the Minister of Health to say that it is understood that the convenience of the Council will, in the first instance at any rate, be met by arrangements under which they continue as at present to be informed of cases of removal from the medical list under Part VI. of the principal Regulations, and are in addition informed of (1) cases of irregular or lax certification; (2) cases of unprofessional conduct; and (3) cases in which allegations of canvassing or fraud are established or substantially supported.
>
> "The Minister will be glad to enter into arrangements on these lines, and he thinks it will be convenient that in bringing cases other than cases of removal from the medical list to the notice of the Council he should forward to them copies of the following documents: the report of the Subcommittee (normally the Medical Service Subcommittee) of the Insurance Committee by whom the matter will have been investigated in the first instance; the decision of the Insurance Committee on that report; the report of the persons who heard the appeal (if any) against the Committee's decision; the representations (if any) made by the practitioner to the Minister under Article 41 of the principal Regulations; and the Department's letter conveying the Minister's decision either to warn or censure the practitioner, or to take action with a view to the withholding of part of the remuneration otherwise payable to him. In cases of lax certification dealt with under Article 3 of the National Health Insurance (Medical Benefit) Amendment Regulations, 1930, the report of the Panel Committee will take the place of the report of the Medical Service Subcommittee."

Similar arrangements are to be made for the communication to the Council of cases arising in Wales and Scotland. At its meeting on Feb. 22nd the Executive Committee of the Council approved the procedure proposed.

which are faced with no problem because the conditions they offer attract all the nurses they require; a keen interest on the part of the leaders of the profession in the education of probationers; and above all a sense of vocation and a professional pride that have so far prevented the shortage of suitable candidates from lowering at all the standards of nursing in the country.

In our recommendations, we have endeavoured to bring together the lessons of the successful experiments that have been made and to suggest changes that will generalise the best existing practice. We have endeavoured to show how the entry to the profession can be linked up with the general system of girls' education, and to indicate measures that should go far to meet the peculiar difficulties of some of the specialised institutions. It would have been as easy as it would have been useless to take the highest standards of remuneration and conditions of other women's occupations and invite the hospital authorities to outbid them, or to recommend conditions that might attract candidates, but would be quite incompatible with the proper fulfilment of the purpose for which the nursing profession exists. It was impressed upon us by all the witnesses best qualified to speak for the profession that a sense of vocation is essential and that the standards of the profession could not be maintained merely by an economic appeal. This we fully accept, provided that it is understood that an aspirant may properly feel a call, not only to render a personal service to individual patients, but equally to take a part in health propaganda or in the important administrative and social work involved in the running of a hospital.

We have sought to eliminate anomalies, unnecessary hardships, and interferences with personal freedom. If other professions are now open to educated women, and occupations of a less exacting and responsible character offer higher or more immediately economic attractions, the inherent importance and interest of the nursing profession remain undiminished. Its status has been raised by the system of State registration and the more regular provision of education in connexion with training. Our survey has revealed no insuperable difficulties, even without revolutionary change, in the way of overcoming the shortage of suitable candidates, and we offer this Report to the authorities directly concerned and to the public, as a contribution to the solution of the problem presented by this shortage.

MEDICINE AND THE LAW.

Unsuccessful Claim against Surgeon for Negligence.

The litigation in Tudor *v.* Mein, heard before Mr. Justice McCardie and a special jury on March 2nd and 3rd, illustrates a typical risk of the profession. A surgeon operated upon a child. Four months later, when the patient is in another part of the country, a second operation is found necessary and is performed by another surgeon. The child's parents, convinced that the first surgeon must have been negligent, sue him for damages. After their case has been placed before a jury with full publicity, the defendant gives his own account of the operation and submits himself to cross-examination. He is followed in the witness-box by two other surgeons who negative the idea of negligence. Thereupon the plaintiff's counsel withdraws all allegations unreservedly, and the parents express through him their appreciation of the fact that the original operation saved their child's life. The defendant surgeon, who had been forced to defend his professional reputation against so damaging a charge, then makes an *ex gratiâ* payment in respect of the plaintiff's costs out of what the learned judge calls "a generous goodwill." The judge emphasises the fact that all allegations of negligence are entirely withdrawn and that it is recognised that the defendant is an able and experienced surgeon. Could not this result have been attained without the time and money expended over full-dress legal proceedings, not to mention the anxiety of the defendant and the interference with his work? The issue here was entirely technical; decision depended on expert opinion. Is it not possible to evolve a tribunal which would sift these claims before they reach a jury? If plaintiffs withdraw their actions on hearing what is said by the other side, could not this process take place earlier? In the action against Mr. Mein we were happily spared the spectacle of expert witnesses for the plaintiff violently attacking the reputation of a member of their own profession. It must sometimes happen that, if the expert witnesses on both sides could get together beforehand, a plaintiff might, on fuller information, discontinue proceedings.

The case against Mr. Mein may be briefly summarised. The original operation was for the removal of the appendix. The plaintiff evidently believed that nothing of the sort was done, since at the second operation the appendix was said to have been found complete. The defendant's answer was that, at the original operation, he found "everything was a mass of adhesions." He enlarged the opening and found the tip of the appendix which was gangrenous and perforated. Four and a half inches from the tip he came to where the appendix appeared to attach itself to the large intestine, and he cut it off at that point. The general practitioner and the nurse, both of whom attended the operation, were present in court and ready to say that they saw the appendix which the defendant removed. Sir Charles Gordon-Watson and Mr. Warren Low gave evidence as to the difficulty of finding the actual position of the join of the appendix and the intestine, when there are adhesions. In some cases, said Mr. Low, it was impossible; he did not suppose there was a surgeon who had *not at some* time been mistaken. This evidence virtually disposed of the claim; the surgeon who performed the second operation had previously agreed that an operator who removed 4½ inches of appendix might well think he had removed the whole.

It remains only to add that, so long as claims of this nature are a risk of practice, it is only prudent to insure against them by joining one of the experienced defence organisations. The defence on this occasion was undertaken by the London and Counties Medical Protection Society, and the defendant's membership must have proved a wise investment.

FINANCES OF THE LONDON HOSPITAL.—In 1931 the income of the London Hospital was £242,153, and the expenditure £250,030, leaving a debit balance of £8777. The expenditure, nevertheless, showed a reduction of £9517, partly due to the greater cheapness of commodities; the income was £1618 greater. The revenues from invested property was £55,241. There were 13,617 in-patients, and 81,380 new out-patients, 1200 of whom were often treated in a day. In recording that the hospital possesses 2 grammes of radium the Governors state that "undoubtedly in certain cases of cancer radium is beneficial." The Viscount Knutsford Remembrance Fund stands at £11,533.

typical reaction followed with headache, diarrhœa, nd vomiting with rise of temperature to 100° F. r 12 hours. The local reactions of the stings were evere and the swellings on face and hands remained or three days.

Dr. X regards his case as an example of sensitisation o bee-stings which persisted for ten months. After his experience his enthusiasm for bee-keeping was omewhat damped, for had he fallen insensible on the op of the hive and received the full dosage of hundreds f stings the result might have been disastrous. It would be interesting, he thinks, to find out whether ther bee-keepers have had a similar experience.

I am, Sir, yours faithfully,

A. L. GREGG.

Porchester-gardens, W., March 5th, 1932.

CHRONIC INFECTIONS OF THE LUNGS.

To the Editor of THE LANCET.

SIR,—The interesting contribution by Dr. P. J. Marett, in your last issue (p. 511) on chronic infections of the lungs by fungi and the importance of the routine mycological examination of sputum to assist in the diagnosis of these infections, whose response to treatment is by no means unfavourable, merits wide recognition. The fungi as ætiological agents in diseases of the respiratory tract have not received the attention which is their due. These pneumonomycoses (moniliasis, blastomycosis, actinomycosis, aspergillosis, &c.) may produce signs, symptoms, and even lung changes which may closely simulate pulmonary tuberculosis. Two such cases of primary monilia infection of the lung were shown by me at the Clinical Section of the Royal Society of Medicine last year. As Dr. Marett points out, the mere presence of monilia in the sputum does not indicate a primary fungous infection. These fungi are, in point of fact, not uncommonly secondary. There can be little doubt that a catarrho-pyogenic infection due to any other organism, including monilia, superimposed upon a case of pulmonary tuberculosis does tend to aggravate the tuberculous process. Treatment of this superimposed infection is often most striking, especially where this is due to a fungus upon which, as is well known, iodide of potassium has a selective action. Hence examination of the sputum in chronic lung infections should not be limited to tubercle bacilli, but should include examination for other organisms, not excluding the fungi.

I am, Sir, yours faithfully,

Harley-street, W., March 7th, 1932. PHILIP ELLMAN.

EUTHANASIA.

To the Editor of THE LANCET.

SIR,—In your kind review of my brochure on the Legalisation of Voluntary Euthanasia (THE LANCET, March 5th, p. 523) you say:—

> "Surely a movement as novel and daring as this has evoked as weighty criticism as it has approbation? If Dr. Millard has received any expressions of adverse opinion at all comparable with the favourable ones he quotes, it would probably help his cause if he were to publish them."

In reply may I say that apart from objections based on religious grounds, such as those quoted in my brochure, I have received remarkably little reasoned criticism—almost none that can be called hostile. One correspondent, whose opinion one is bound to respect, writes:—

> "You certainly make out a good case but not, I think, an unanswerable one. It seems to me that you underestimate the natural reluctance of members of the medical profession to assume the responsibility that would fall upon them; nor do I think that the possibilities of crime are eliminated. . . . I should estimate that very few doctors would pronounce any disease incurable until it was a matter only of a short time."

Of helpful criticism—if indeed it can be called criticism—the most important is from a high legal authority in London (owing to his official position he does not wish his name to appear), who has made several sympathetic and friendly suggestions as regards the legal aspect of my Bill. He doubts whether it is really necessary for applications for euthanasia to go before a court of summary jurisdiction, and he rightly points out that such a tribunal would not be the best fitted for the purpose. He thinks that it would be a sufficient safeguard if the "near relatives" had the right of appeal to such a court, which right in practice would probably be very rarely exercised. I am quite prepared to accept this suggestion. This gentleman has been at the trouble of redrafting and amending my Bill, adding the necessary legal definitions, schedule, forms of medical certificates, &c. Thanks to his legal knowledge and special experience in drafting Bills, this new Bill is undoubtedly a much better Bill than mine, and when the time comes for this question to be raised in Parliament the Bill is all ready to be put forward.

Of warm approbation I have received far more than I ever dared to hope or expect. A letter received this morning from the principal of a university college may be cited as an example: "I am intensely interested in your proposals, which I believe in completely." A distinguished member of our profession wrote me the other day: "I am in complete sympathy with your proposals, both on humanitarian and sociological grounds. . . . I wish you every success."—I am, Sir, yours faithfully,

C. KILLICK MILLARD.

Health Department, Grey Friars, Leicester, March 8th, 1932.

RELIEF OF VESICAL IRRITATION.

To the Editor of THE LANCET.

SIR,—The method described in your annotation last week (p. 524) apparently depends upon the use of mineral oil, and is described as a simple one, with claims so striking that it deserves a trial. If you will refer to your own issue of 1924, i., 179, you will find, related by myself, a technique for cystoscopy in the presence of pus and blood in which mineral oil is used as the medium. Experience has amply justified the hopes expressed when the method was first tried out. Bleeding from a papilloma in the bladder can be readily located and easily cauterised by the diathermy electrode. Mr. Canny Ryall, in his book "Operative Cystoscopy," states that in this way he has been able to deal with hæmorrhage which he could not otherwise have arrested. This is fully borne out by my experience.

Support can also be given to the statement that vesical irritation after cystoscopy and diathermy is much less than after ordinary methods. Selection of the grade of paraffin is, however, important, since liquid paraffin of the British Pharmacopœia, however useful in treatment, is too viscous for satisfactory use with the cystoscope. Oils of a low viscosity are much more suitable and easier to use.

I can most strongly recommend the method in indicated cases.—I am, Sir, yours faithfully,

W. E. M. WARDILL.

Newcastle-upon-Tyne, March 7th, 1932.

CORRESPONDENCE

TUBERCULOSIS OF CHILDHOOD.

To the Editor of THE LANCET.

SIR,—The interesting letter of Drs. Toussaint and MacIntyre raises the question of the relative value of radiography and tuberculin in the diagnosis of infantile tuberculosis. Their high opinion of the tuberculin test is rightly based on the recent report of the Medical Research Council, but their opinion of radiography is based on obsolete conclusions of a committee of the National Tuberculosis Association of America. The conclusions of this committee were made at a period when there were wide variations in radiographic technique. In the light of recent knowledge these conclusions should be revised as follows :—

> "The normal chest.—The normal chest of the child from the roentgenological standpoint is subject to no more variations than the normal hand.
>
> "Hilum shadow.—The hilum shadow in health is cast by the pulmonary artery only. Normal glands, bronchi, and veins play no part in the formation of this shadow. Glands only become visible when caseating or grossly enlarged, and are then easily identified as such.
>
> "Calcified nodes.—Calcified nodes at the root of the lung, irrespective of signs of lung disease, are definite evidence of old tuberculosis in the bronchial glands. There is no inflammatory condition except tuberculosis which causes dense calcification of the bronchial glands."

Drs. Toussaint and MacIntyre consider two of Dr. Fletcher's cases to be "incompletely resolved pneumonic conditions," and then state that "such cases are far from rare in tuberculosis dispensaries with adequate X ray facilities." In other words, there is a form of pneumonia in children which can only be diagnosed by radiography, and which is not acute inasmuch as the sufferers from it are brought to tuberculosis dispensaries. A considerable number of these "pneumonic conditions" in children have been observed in the Royal Chest Hospital, and there are certain features common to them all. The children are never acutely ill, and often have no pyrexia. The pneumonic processes observed by serial radiographs slowly resolve or calcify. What organism other than the tubercle bacillus produces a chronic and often symptomless pneumonia which can heal by calcification ?

I am, Sir, yours faithfully,
PETER KERLEY.
Weymouth-street, W., March 5th, 1932.

BLOOD TRANSFUSION IN PURPURA.

To the Editor of THE LANCET.

SIR,—In their article in your last issue (p. 509) upon Hæmorrhagic Purpura following Scarlet Fever, Dr. A. G. Gibson and Dr. F. G. Hobson state that transfusion of blood was considered in the second case, but, in view of the fact that the patient's serum agglutinated her own red cells and those of all possible donors, this procedure was, in consultation with Dr. Letheby Tidy, deemed to be impossible. May I recall two cases reported in your own columns (1931, ii., 399) by Dr. W. Stewart and myself in which transfusions of blood were given to patients in this hospital, both of whose sera agglutinated their own and all other red cells against which they were tested. Dr. S. C. Dyke demonstrated this phenomenon to be dependant upon temperature and to bear no relationship to blood group, and on his advice transfusion was performed in both cases with group-compatible blood. In both instances the transfusion was followed by a sharp reaction which was however readily controlled by adrenalin and morphia.

I am, Sir, yours faithfully,
EILEEN E. HARVEY, M.R.C.S. Eng.,
Assistant Pathologist, the Royal Hospital,
March 7th, 1932. Wolverhampton.

ANAPHYLAXIS FROM BEE-STINGS.

To the Editor of THE LANCET.

SIR,—That repeated bee-stings lead to an immunity from ill-effects is exemplified by seasoned apiarists. As yet however we have no adequate explanation for the sudden loss of this immunity which has been known to occur in even veteran bee-keepers, when without warning they have suddenly been seized with acute symptoms following a few stings which would ordinarily occasion them not a moment's notice. Simmins [1] states that the beginner at bee-keeping occasionally "is so severely punished, even by a solitary sting, that he may begin to think seriously of giving up. In a few instances the difficulty is never overcome ; but, as a rule, the apiarist becomes in time, not only used to, but quite careless of bee-stings." The actual prick however always remains painful. Herrod-Hempsall [2] mentions that "there are a few people who cannot keep bees on account of the effect of the sting upon them. In some cases the poison causes temporary distress in the form of asthma, in others a state of coma occurs, while yet again a fainting fit may result." The Roots [3] describe the occurrence of a rash of red blotches following stings, accompanied by fever ; and they cite an interesting case of a boy originally severely affected by stings who was cured of ill-effects by a course of graduated numbers of stings at intervals throughout a year.

As an example of the severe reaction which may occur, the following description by a medical friend seems to me worthy of being placed on record. Dr. X has been interested in the keeping of bees for the last two years. In August, 1930, he was "stung up" whilst, perhaps from clumsiness and inexperience, he irritated the hive to the point of frenzy. Although well protected by bee-veil and gloves, he received over 20 stings which resulted in local and systemic reactions, so that after a mild rigor he had to retire to bed with headache, diarrhœa, and general disfigurement. Subsequent to this, although conscious that the bees loved him not, he remained comparatively unmolested till June 7th, 1931. On that occasion whilst, with due preparation, he was engaged in a simple operation on his hive, he was stung on the chin and forearm by three angry bees. It was noted that the stings were particularly painful. Within ten minutes he experienced a cramping pain over the præcordial region and a curious sinking feeling radiating down the thoracic aorta. At the same time the pleasant surroundings, including the hive itself, appeared to revolve round and round in kaleidoscopic confusion. Enough consciousness remained to enable him to stagger some 40 yards from the hive when he collapsed on the garden path and there he remained unconscious for 20 minutes.

1 to ice-cream, for they did not know in all where the premises were situated in which ges were made. This was a public health ion, and what the Council wanted to do was to ct the food of the people. Therefore they ed to have the same powers with regard to ges and preserved meats, &c., as they were now g for in connexion with ice-cream. The London igh councils and the city corporation were all d that Clause 16 was necessary in order to round eir powers for preserving the health of the people. e powers were necessary to keep traders up to nark.

. **Lansbury** said he wished to join with other lon Members in saying that these clauses were ed unanimously by all the representatives of lon. Before any regulations existed in regard to matters the medical officer of health in his area continually telling him of things which he had ower to interfere with.

JUSTMENT OF PUBLIC HEALTH TO LEGITIMATE TRADING.

r E. **Hilton Young** (Minister of Health) said the ers sought for by the London County Council er this Bill were certainly not without precedent, those conferred by Clause 16, which raised so h contention. He knew of no record of any culty or friction or dissension or complaint of stice in the past. Powers that had been found ul and had given rise to no complaint in provincial s might well be useful and necessary in the ropolitan area. In this matter it was necessary adjust two very substantial interests. The first that of public health, and he could not help ig impressed by what had been said by several akers in the debate upon the big interests of public lth involved in the powers now sought by the adon County Council. On the other hand, he had n impressed by the fact that the interests of itimate trading were also involved, which the use would be concerned to safeguard. The justment of those two interests was a matter which eded very careful threshing out by a committee, her than on second reading. He had come to the nclusion that the House would be well advised t to reject the Bill at that stage, but to consider e general discussion as giving notice to the important terests involved, and to leave it to the committee adjust those interests later. The Bill contained any things in the interests of the good government London, and it would be a little out of proportion reject it as a whole when there was a possibility of ljusting matters in committee.

Mr. **Cassels**, speaking as a London Member, said at there was already ample provision in the law of le land to deal with unwholesome food. Why did le London County Council in the interests of public ealth desire to have such a full and complete inspecon of everybody's premises? Traders did not want he whole of their premises continually roamed over y inspectors under various labels. While the House ught to have the interest of public health at heart, hey ought to say that the existing law was quite ufficient, even for the London County Council.

Clause 18.

Dr. **O'Donovan** said there was an interest which had not been referred to that night—namely, the poor individuals who had the whole of Clause 18 of this Bill devoted to them. He had no objection as a London Member to any attempt to see that the food consumed by the poor should be brought up to the standard that Members would demand in their own houses, and he would be the first to say that the public health work done by the borough councils, their medical officers of health, and other officials in London was an example to the world; but in every ointment, however healing, a fly could find its place. They were instructed in this Bill that "every medical practitioner" shall, if he suspects, do certain things. It was extraordinary that the Bill did not say "every registered practitioner," and they would perhaps find herbalists, bone-setters, and faith-healers, on the strength of this wording, claiming the status of a medical practitioner. He had thoughts to which he desired to give utterance, and thoughts which he suppressed, but in this Bill every medical practitioner, and no one else, must sign his suspicion if he suspected food poisoning. He was accustomed to notifying small-pox if he believed it to be present, but that he should be compelled to notify the suspicion of disease that might cross his mind was rather too much. If he suspected food-poisoning, in the hard-hearted language of the law he must notify it by certificate forthwith.

DOCTORS AS INITIATORS IN CRIMINAL PROSECUTIONS.

If notification were for the good of the public health he would willingly notify, not on paper but by telephone, but he gathered that the London County Council was out to punish those who poisoned Londoners, and the suspicion of a doctor put upon paper might be the first instrument by which the wheels of punishment were put in motion. He asked the House to put themselves in the position of a simple honest practitioner of medicine who committed these suspicions to papers and then someone died. These matters often raised great doubt and controversy, and yet in its zeal, and proper zeal, for the guardianship of the public health, the proper authority might decide to have an investigation. What was then the position of a doctor who had committed his suspicions to paper when he was being cross-examined by the most skilful counsel that the Food Trade Association could put up to humble his suspicions to the dust?

DELAYED PAYMENT.

Furthermore there was perpetuated in this Bill an extraordinary wrong. A doctor could be assessed at two separate values. He was worth under this Bill 2*s.* 6*d.* if he was a practitioner, free and unpanelled; but if he took service under an authority and became a medical officer, or if he worked for nothing in a dispensary or a hospital, his suspicion or opinion was worth not 2*s.* 6*d.* but 1*s.* (Laughter.) He noticed that although the practitioner must notify forthwith, nevertheless there was no arrangement for payment forthwith, and it was the practice of many local bodies to accumulate these small debts, these half-crowns or shillings that were very acceptable to very young doctors starting in practice, and then to send a cheque six or nine months afterwards when the doctor had left the hospital, and the cheque became a derelict. An act which was compulsorily done forthwith should be paid for forthwith.

"EVERY PRACTITIONER ATTENDING."

It was not uncommon in difficult cases for doctors to be called in consultation, and hitherto in cases of notification there was no compulsion upon a consultant to notify. He gave his opinion to the doctor in attendance, and that was his liability; but this Bill said "every medical practitioner attending," and in drawing all the doctors in it missed the most useful source of information by its very precision of words, for often food-poisoning was not known till death, and the doctor who diagnosed food-poisoning at its deadliest and most dangerous point was not the medical practitioner in attendance, but a pathologist, and a pathologist who might let them know at the very beginning of a fatal epidemic was excluded from the Bill. He had every sympathy with the purpose of the Bill, but in this particular clause he would ask the House to remember that they were throwing upon his profession without intention a certain responsibility in criminal proceedings. They were making the medical profession initiators of criminal prosecutions on suspicion for a fee of a shilling, and there was no defence in the Bill for an honest mistake made by a man who might not be a shining light in the healing art.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

THE WHEAT BILL.

In moving the second reading of the Wheat Bill on March 1st in the House of Commons Sir **John Gilmour** (Minister of Agriculture) said that the measure was agreed to by all the interests concerned. The Government did not contemplate that there would be a permanent increase in the price of bread as a result of this Bill, and they were satisfied that, with a maximum limit of 6,000,000 qrs., there was no danger that a permanent general increase in bread prices would result. It was, he said, only when flour and bread were cheap that the quota payment on flour was really noticeable. To-day United Kingdom consumers of flour and bread got them at lower prices than any other country in the world, except possibly Belgium.

Dr. **Salter**, who moved the rejection of the Bill, said that it was the bread consumer who was to pay the price. Bread was still the cheapest all-round food, and the poorer the family the more bread they consumed. There were, he said, hundreds of thousands of families in this country whose bread bills were over 10*s.* per week, and almost all were the very poorest people. He described the policy of the Bill as an attempt to revert to a condition of affairs in English life which had long since passed away and which could never be restored. The motion for rejection was defeated by 428 votes to 55—majority 373—and on March 2nd the Bill was read a second time and committed to a Committee of the whole House.

DANGEROUS DRUGS BILL.

On Wednesday, March 2nd, in the House of Lords, the Dangerous Drugs Bill was read the third time.

LONDON COUNTY COUNCIL BILL:

FOOD INSPECTION PROPOSALS.

In the House of Commons on Thursday, March 3rd, on the motion for the second reading of the London County Council (General Powers) Bill,

TRANSPORT OF EDIBLES

Mr. G. **Harvey** moved the rejection of the Bill. He said that two clauses in particular struck him as being unfair to the trading community of London. With regard to Clause 17, within the last day or two a concession had been made by the London County Council. It said:—

> "The London County Council is prepared to give an assurance to the following effect in the event of the opposition to this Bill being withdrawn."

That was a passage he did not like. The concession went on:—

> "Any by-laws proposed to be made by the Council in pursuance of Clause 17 shall not extend beyond the scope of Section 72 of the Public Health Act, 1925, subject to the inclusion of by-laws to deal with two additional matters, namely: (i) Arrangements to ensure cleanliness, &c., in transport: It would be understood that transport does not include [illegible] curtilage of the customer's premises. [illegible] cases in which food is wrapped in paper [illegible] wrapping shall be clean and otherwise [illegible]"

The Public Health Act, 1925, expressly excluded London, and in proposing to make by-laws in pursuance of this clause the Council met the difficulty of a good many of those who objected in the first instance. But if Section 72 of the Public Health Act, 1925, were made to apply, in his view and those who were advising him Clause 16 would not be necessary at all.

REGISTRATION OF THE SMALL TRADER.

The London County Council stated with regard to Clause 17 that some 60 provincial boroughs had adopted by-laws under the powers given to them by the Public Health Act, 1925. When the Council was asked to give a list of those 60 boroughs the number resolved itself into 17. These were written to, and only three had thought fit to utilise the power to make by-laws. Clause 16 referred to further registration requirements, and Subsection (2) was in the nature of an attempt to browbeat the small trader. The Statutory Rules and Orders, No. 1432, under the Public Health Act referring to meat set out in detail the sanitary arrangements of shops, stores, and other places in which meat was sold, or exposed for sale, and he would have thought that that ample provision would have been sufficient without further attacking traders who were trying to do their best in very difficult conditions. Under Clause 16 all meat shops had to be registered if they dealt in potted, pressed, pickled, or preserved meat, but there was no definition of those commodities in the Bill. He thought that to require a meat shop to be registered when clubs, hotels, and restaurants were exempted was quite unnecessary. The following officers had the right to inspect meat traders' premises—the meat inspector, the sanitary inspector, the medical officer of health, the shops inspector, the inspector of weights and measures, in some cases the factory inspector, the inspector from the Ministry of Labour, the inspector from the Ministry of Health, the inspector under the Food and Drugs Act, and the inspector of juveniles. Now it was proposed to add the sausage-making inspector. (Laughter.) The time was arriving when this over-inspection was becoming the bugbear of all who attempted to carry on any business.

Mr. **Herbert Williams** seconded the motion for rejection. He said none of those who opposed the Bill desired to hinder the London County Council in their splendid and beneficent work, and he appealed to the promoters to give them some reasonable undertaking with respect to Clause 16 similar to that which they had given in the matter of Clause 17.

FURTHER POWERS REQUIRED BY THE L.C.C.

Sir **Cyril Cobb** said he could give an undertaking that the by-laws which would be drawn up in due course would be drafted under Section 72 of the Public Health Act, 1925. He could not meet, however, the desire of Mr. Harvey and Mr. Williams in regard to Clause 16. The Council must have registration, and must have the necessary powers to see that such registration was effective. Clause 16 dealt with ice-cream and sausages. The Council had registered ice-cream makers since 1928, but they had not previously registered sausage-makers. At present they could do nothing against the ice-cream maker unless he refused to be registered and still went on making ice-cream; in that case they could proceed against him. They could also proceed against him if he poisoned anybody, and information of it was brought to their notice through the medical officer of health. They could not take him off the list of registered ice-cream makers, and could not refuse to register him, even though they knew from the beginning that his premises were uncleanly and insanitary. Therefore, it was necessary for them to have the further powers asked for under the Bill. At present, so far as they were able to deal with sausage-makers at all, they were obliged to fall back on the ordinary regulations of the Ministry of Health regarding food, and on the Public Health Act (London), 1891. Under that Act any medical officer of health, or sanitary inspector, might at all reasonable times enter all premises and inspect and examine any animal intended for the food of man which was exposed for sale or deposited in any place for sale or preparation for sale; also any article, whether solid or liquid, intended for the food of man, and sold, or exposed for sale, or deposited in any place for sale, or preparation for sale. At present they were in a worse position with regard to sausages than with abroad, which had been pasteurised once before tation and a second time after importation, had been n this country as pasteurised milk.—Sir E. HILTON G replied: The inquiries made by officers of my tment have afforded no evidence that any such milk een sold in this country as "pasteurised milk."

Child Adoption.

. LOVAT-FRASER asked the Minister of Health if his tion had been called to the fact that in some cases -parents who took children under the Children Act, , were paid lump sums and then disappeared, leaving hildren chargeable to the public assistance committee; whether he proposed to take legislative steps to prevent in future.—Sir E. HILTON YOUNG replied: No cases e kind described have been brought to my notice.

Vaccination Declarations.

. GROVES asked the Home Secretary whether his tion had been called to the refusal of certain London ndiary magistrates to take statutory declarations under Vaccination Act, 1907, when sitting in open court; whether he would send a communication to the London ndiary magistrates on this subject.—Sir H. SAMUEL ed: My department has received no complaints of the re indicated for some time past.

National Radium Trust.

r. JOHN asked the Minister of Health if he would furnish res of the receipts and expenditure of the National ium Trust up to Dec. 31st, 1931.—Sir E. HILTON YOUNG ied: I am informed by the National Radium Trust the total amount received by the Trust from its inception in July, 1929, to Dec. 31st, 1931, from public subscrip s, moneys voted by Parliament, and interest on porary investments, was £258,536 13*s.* 1*d.* The payments le in the same period (excluding those made by way of porary investment) were as follows:—

	£	s.	d.
chase of radium and containers	217,726	11	2
vances to Radium Commission	2,700	0	0
ting and measurement of radium	1,616	0	0
er expenses of the Trust	562	8	2
Total	£222,604	19	4

Prevention of Thames Floods.

Mr. MOREING asked the Minister of Health when it was pected that the departmental committee on Thames oods Prevention would resume its sittings; and how soon would issue its report.—Sir E. HILTON YOUNG replied: e work of this and various other committees was suspended a measure of economy. I propose to take the question resumption into consideration at an early date.

Telephone Subscribers and Deafness.

Major JESSON asked the Postmaster-General whether, aving regard to the fact that at least 20 per cent. of telephone sers suffered from deafness to a degree that prevented em from hearing the muffled sound of the double bell t present in universal use, he would consider its replacement y a single bell of more resonant quality.—Mr. GRAHAM HITE (Assistant Postmaster-General) replied: Experience ndicates that the ringing apparatus normally supplied eets the requirements of subscribers generally. Further bell of different pitch which is found to be more suitable n certain cases is supplied without charge, and an extension ell with a larger gong is provided at an additional charge hen desired.

MONDAY, MARCH 7TH.

The Indian Medical Service.

Mr. KIRKPATRICK asked the Secretary for India if he was aware that there was a feeling of uncertainty and apprehension among officers of the Indian Medical Service as to the security of their pensions; and whether the British Government guaranteed those pensions.—Sir S. HOARE replied: I am aware that there is, and has for some time been, some anxiety among officers of the Indian Services generally as to the security of their pensions, though I have not received any special representations from officers of the Indian Medical Service. The pensions of officers of the Indian Services are not guaranteed by the British Government; they are a charge on Indian revenues, and the responsibility for ensuring that the necessary funds are forthcoming rests with the Secretary of State for India. The Services subcommittee of the Indian Round Table Conference recommended that when a new constitution for India is drawn up, suitable safeguards for the payment of pensions should be provided, and the Prime Minister, in the statement made by him on behalf of His Majesty's Government, at the final meeting of the first conference, laid it down that the transfer to a responsible Government in India of responsibility for the finances of that country must necessarily be subject to such conditions as would ensure the fulfilment of the obligations incurred under the authority of the Secretary of State and the maintenance unimpaired of the financial stability and credit of India. The consent of Parliament would be required to any change in the present position, and it is inconceivable to the present Government that in dealing with any scheme of constitutional change in India, Parliament could fail to provide such safeguards as may be necessary to ensure due payment of pensions to officers who have served the country.

First-aid and Medical Aid in India.

Mr. PARKINSON asked the Secretary for India what arrangements were made by the authorities to give first-aid and medical attention to those injured by lathi charges or rifle fire.—Sir S. HOARE replied: The reports received by me show that the senior officers present are always careful to ensure that injured persons receive attention, and, when necessary, are conveyed to the nearest hospital or dispensary at the first opportunity.

Closing of Pensions Hospitals.

Mr. LOGAN asked the Minister of Pensions what Ministry hospitals had been closed in the past 12 months; and whether it was proposed to close further hospitals and make arrangements for pensioners to be treated in hospitals near their own homes on a capitation basis.—Major TRYON replied: Four hospitals—namely, Fernbank near London, Highbury Hospital, Birmingham, Blackrock Hospital, Dublin, and Kirkburton, an institution for mental cases near Huddersfield—have been closed during the past 12 months. Another institution may be closed in the current year if alternative arrangements for the treatment of patients can satisfactorily be made. The policy of the Ministry is to make use of civil hospitals as far as possible consistently with the interest of the Ministry's patients, but there are certain types of disability, as, for example, epilepsy, mental disorder, and neurasthenia, and certain types of surgical case, for which specialised arrangements or institutions are desirable in the interest of the patients.

Milk and Milk Products Commission.

Dr. CLAYTON asked the Minister of Agriculture whether he proposed to appoint a reorganisation commission for milk and milk products.—Sir JOHN GILMOUR replied: Yes, Sir.

Hypodermic Syringes for Panel Patients.

Dr. O'DONOVAN asked the Minister of Health what were the regulations governing the prescription and supply of hypodermic syringes to patients suffering from asthma under the care of practitioners on the panel and needing such syringes for self-treatment.—Sir E. HILTON YOUNG replied: The appliances in question are not included in the list of appliances contained in the Second Schedule to the Medical Benefit Consolidated Regulations, 1928, and cannot, therefore, be supplied as part of medical benefit.[1]

TUESDAY, MARCH 8TH.

Pithead Baths.

Mr. PRICE asked the Secretary for Mines the number of coal-mines furnished with pithead baths in each mining area of England, Scotland, and Wales; and the number of cases in which these had been provided out of the Miners' Welfare Fund.—Mr. ISAAC FOOT replied: The total number of coal-mines in England, Scotland, and Wales furnished with pithead baths for workmen is 103. Of these baths, 85 were provided out of the Miners' Welfare Fund, and six were partially paid for by the Fund. In addition, 41 installations, all provided out of the Fund, are in course of construction.

---

[1] See THE LANCET, Feb. 20th, p. 421.

HAMPSHIRE HOSPITALS.—According to the annual report of the Royal Hampshire County Hospital there were last year 2627 in-patients, an increase of 224; 2001 of them were operated upon. They were thus distributed: men, 732; women, 1072; children, 823. There were 6220 out-patients, an increase of 184, of whom 768 were operated upon. The total average cost of each patient has fallen from £9 3*s.* 3*d.* to £8 4*s.* 8*d.*—The Royal South Hants and Southampton Hospital last year reduced the weekly cost per patient from £2 18*s.* to £2 16*s.* 4*d.* The overdraft of £59,000 has been reduced to £18,000 by the sale of securities.

DIFFICULTIES OF NOTIFICATION.

Captain FRASER said that the House ought to be sure that the provisions of this Bill were workable. There were various forms of food-poisoning. There was botulism, a very rare form, and one hardly contemplated by the provisions of the Bill. Then there were those forms of poisoning due to poisonous substances being added to food, either for the purpose of preserving the food, and which in excess became poisonous, or which were due to accident. Many cases of so-called food-poisoning arose from these causes, but they were all very slight. The inspectors or medical men would be going on an entirely blank trail if they made any inquiries about them. Then there was the commonest form of food-poisoning at which this Bill doubtless was directed, which was produced by the Gaertner bacillus. That particular bacillus existed in clean as well as in dirty surroundings. The mere removal of dirty surroundings would not remove the possibility or probability of the bacillus being present. It was present in certain kinds of meat and in rodents. It was also present in human beings. It poisoned immediately because the bacillus had put poison into the tissue of the meat, and the poison entered into the human being who had absorbed it. No inspector could find that out by mere insistance on cleanliness. Moreover, there were persons who were carriers of this particular bacillus. They became immune, but they could transmit the bacillus to any food they touched. This Bill would not do what was claimed for it. In the first place it would involve too great an expense, and the community could not afford what might have been desirable two or three years ago; secondly, there was no proof that it would be of the slightest use; and thirdly, there had not been time over a wide enough area for full criticism and complaint to have come forward. Never before had a medical man been asked to notify a disease which was so ill-defined as food-poisoning. He did not think that the mere patching up of these clauses in Committee would meet the case. On every ground Clause 18 ought to be withdrawn. The L.C.C. in the defence of their proposals told them that there were 11 deaths in three years. Yet this vast machinery was to be set up to prevent the recurrence of those cases. He would not mind expenditure to save life, but the accumulation of this kind of expenditure threatened life by making life intolerable for the people. The London County Council could get their Bill through swiftly if they would leave out the offending clauses.

MUCH UNCLEANLINESS.

Mr. LOGAN said he knew the benefits from a sanitary point of view which had been derived in Liverpool from registration under the Public Health Act. Had it ever occurred to hon. Members how much uncleanliness there could be in a great city like London in the production of ice-cream and foodstuffs? They allowed health visitors to see if houses were kept clean and not overcrowded, and yet if one bought an ice-cream in London they were not able to tell the purchaser whether it was made in a stable or in a palace. He thought that the London County Council and the sanitary authorities of London were perfectly justified from the point of view of public health in asking for these powers.

Mr. G. HARVEY said that in view of the desire of the Minister of Health that the matters raised in the debate should be thrashed out in Committee, and in view of the desire of those who objected to certain clauses of the Bill not to hamper in any way reasonable operations on the part of the L.C.C., he asked leave to withdraw his motion for rejection.

The amendment was withdrawn, and the Bill was read a second time.

VETERINARY SURGEONS BILL.

On Friday, March 4th, in the House of Commons, the Veterinary Surgeons (Irish Free State Agreement) Bill, which has already passed through the House of Lords, was read a second time.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 2ND.

Health Insurance Expenditure.

Mr. BUCHANAN asked the Minister of Health the number of persons weekly receiving health insurance benefit, and if the amount was showing an increase or a decrease since the issue of leaflets and instructions to approved societies, doctors, and burgh insurance committees at the end of 1929.—Mr. ERNEST BROWN (Parliamentary Secretary to the Ministry of Health) replied: The rate of expenditure shows a decrease, and it may be inferred that there is also decrease in the numbers.

Mr. BUCHANAN asked if the hon. gentleman could state the actual decrease.

Mr. BROWN: The decrease in numbers could not be stated without examining the records of nearly 8000 approved societies. As regards the amount, the figures will be available in July when the report is published.

Sir P. HARRIS: Does this mean that there has been a general improvement in the [illegible]

Mr. BROWN: I should like to have [illegible]

Mr. BUCHANAN: Is the [illegible] circular, or are there other factors; and is not a decrease contrary to what would be expected, seeing that when unemployment is great sickness usually increases?

Mr. BROWN: The hon. Member would be unwise to draw the conclusion that the circular is the only factor to be considered.

West Middlesex Sewage Scheme.

Mr. MCENTEE asked the Minister of Health if it was at the request of the Ministry that the West Middlesex sewage scheme had been suspended; and whether, having regard to the need for this scheme and the number of persons who would be employed, he would urge the Middlesex County Council to proceed with the undertaking.—Sir E. HILTON YOUNG replied: I am informed that the West Middlesex sewage scheme has not been suspended. Nine contracts of a total value of well over 1¼ million pounds, have been entered into by the county council, six of which are in active operation. Not less than 725 men are already employed on the scheme.

THURSDAY, MARCH 3RD.

Bread Prices.

Mr. D. FOOT asked the Minister of Labour the present comparative price of the 4 lb. wheaten loaf in the following countries: Great Britain, France, Germany, Belgium, Austria, Czechoslovakia, the United States of America, Canada, Australia, Ireland, South Africa, Norway, and Sweden.—Sir H. BETTERTON (Minister of Labour) replied: The latest figures available as to the average prices of white bread in the countries named are given in the Table. In the absence of information concerning the qualities of bread to which the various quotations relate, it is not known how far the prices shown may be regarded as comparable one with another.

Country.	Date.	Average price per 4 lb. of white bread.
Great Britain and Northern Ireland (general average) ..	Feb. 1st, 1932.	7d.
France (Paris)	January, 1932.	4·09 francs.
Germany (6 large towns)	,, 1931.	1·49 reichsmarks.
Belgium (Brussels) ..	,, 1931.	3·16 francs.
Austria (Vienna) ..	Middle of January, 1932.	2·82 schillings.
Czechoslovakia (general average)	December, 1931.	4·2 korunas.
United States of America (51 towns)	Dec. 15th, 1931.	28·8 cents.
Canada (69 towns) ..	Beginning of December, 1931.	24 cents.
Australia (6 large towns)	Sept. 15th, 1931.	7·2d. to 10·9d.
Irish Free State (general average).	Middle of November, 1931.	8d.
Union of South Africa (9 towns)	December, 1931.	14·72d.
Norway (general average)	November, 1931.	1·25 kroner.
Sweden (49 towns) ..	January, 1932.	1·35 kroner.

Note.—The figures given are taken from official publications of the countries concerned, except in the case of Germany and Belgium, for which countries they are extracted from the "International Labour Review," published by the International Labour Office, which is the only available source of information as to the price of white bread in those countries.

Imported Milk and Public Health.

Mr. KIMBALL asked the Minister of Health whether any action had been taken to discover if fresh milk imported abroad, which had been pasteurised once before ation and a second time after importation, had been n this country as pasteurised milk.—Sir E. HILTON G replied: The inquiries made by officers of my tment have afforded no evidence that any such milk een sold in this country as "pasteurised milk."

Child Adoption.

. LOVAT-FRASER asked the Minister of Health if his tion had been called to the fact that in some cases -parents who took children under the Children Act, were paid lump sums and then disappeared, leaving hildren chargeable to the public assistance committee; whether he proposed to take legislative steps to prevent in future.—Sir E. HILTON YOUNG replied: No cases e kind described have been brought to my notice.

Vaccination Declarations.

. GROVES asked the Home Secretary whether his tion had been called to the refusal of certain London ndiary magistrates to take statutory declarations under Vaccination Act, 1907, when sitting in open court; whether he would send a communication to the London ndiary magistrates on this subject.—Sir H. SAMUEL ed: My department has received no complaints of the re indicated for some time past.

National Radium Trust.

r. JOHN asked the Minister of Health if he would furnish es of the receipts and expenditure of the National ium Trust up to Dec. 31st, 1931.—Sir E. HILTON YOUNG ied: I am informed by the National Radium Trust the total amount received by the Trust from its incep- in July, 1929, to Dec. 31st, 1931, from public subscrip- s, moneys voted by Parliament, and interest on porary investments, was £258,536 13*s.* 1*d.* The payments le in the same period (excluding those made by way of porary investment) were as follows:—

	£	*s.*	*d.*
chase of radium and containers	217,726	11	2
vances to Radium Commission	2,700	0	0
ting and measurement of radium	1,616	0	0
ler expenses of the Trust	562	8	2
Total	£222,604	19	4

Prevention of Thames Floods.

Mr. MOREING asked the Minister of Health when it was pected that the departmental committee on Thames oods Prevention would resume its sittings; and how soon would issue its report.—Sir E. HILTON YOUNG replied: le work of this and various other committees was suspended a measure of economy. I propose to take the question resumption into consideration at an early date.

Telephone Subscribers and Deafness.

Major JESSON asked the Postmaster-General whether aving regard to the fact that at least 20 per cent. of telephone sers suffered from deafness to a degree that prevented hem from hearing the muffled sound of the double bell t present in universal use, he would consider its replacement y a single bell of more resonant quality.—Mr. GRAHAM VHITE (Assistant Postmaster-General) replied: Experience ndicates that the ringing apparatus normally supplied eets the requirements of subscribers generally. Further bell of different pitch which is found to be more suitable n certain cases is supplied without charge, and an extension ell with a larger gong is provided at an additional charge when desired.

MONDAY, MARCH 7TH.

The Indian Medical Service.

Mr. KIRKPATRICK asked the Secretary for India if he was aware that there was a feeling of uncertainty and apprehension among officers of the Indian Medical Service as to the security of their pensions; and whether the British Government guaranteed those pensions.—Sir S. HOARE replied: I am aware that there is, and has for some time been, some anxiety among officers of the Indian Services generally as to the security of their pensions, though I have not received any special representations from officers of the Indian Medical Service. The pensions of officers of the Indian Services are not guaranteed by the British Government: they are a charge on Indian revenues, and the responsibility for ensuring that the necessary funds are forthcoming rests with the Secretary of State for India. The Services subcommittee of the Indian Round Table Conference recommended that when a new constitution for India is drawn up, suitable safeguards for the payment of pensions should be provided, and the Prime Minister, in the statement made by him on behalf of His Majesty's Government, at the final meeting of the first conference, laid it down that the transfer to a responsible Government in India of responsibility for the finances of that country must necessarily be subject to such conditions as would ensure the fulfilment of the obligations incurred under the authority of the Secretary of State and the maintenance unimpaired of the financial stability and credit of India. The consent of Parliament would be required to any change in the present position, and it is inconceivable to the present Government that in dealing with any scheme of constitutional change in India, Parliament could fail to provide such safeguards as may be necessary to ensure due payment of pensions to officers who have served the country.

First-aid and Medical Aid in India.

Mr. PARKINSON asked the Secretary for India what arrangements were made by the authorities to give first-aid and medical attention to those injured by lathi charges or rifle fire.—Sir S. HOARE replied: The reports received by me show that the senior officers present are always careful to ensure that injured persons receive attention, and, when necessary, are conveyed to the nearest hospital or dispensary at the first opportunity.

Closing of Pensions Hospitals.

Mr. LOGAN asked the Minister of Pensions what Ministry hospitals had been closed in the past 12 months; and whether it was proposed to close further hospitals and make arrangements for pensioners to be treated in hospitals near their own homes on a capitation basis.—Major TRYON replied: Four hospitals—namely, Fernbank near London, Highbury Hospital, Birmingham, Blackrock Hospital, Dublin, and Kirkburton, an institution for mental cases near Huddersfield—have been closed during the past 12 months. Another institution may be closed in the current year if alternative arrangements for the treatment of patients can satisfactorily be made. The policy of the Ministry is to make use of civil hospitals as far as possible consistently with the interest of the Ministry's patients, but there are certain types of disability, as, for example, epilepsy, mental disorder, and neurasthenia, and certain types of surgical case, for which specialised arrangements or institutions are desirable in the interest of the patients.

Milk and Milk Products Commission.

Dr. CLAYTON asked the Minister of Agriculture whether he proposed to appoint a reorganisation commission for milk and milk products.—Sir JOHN GILMOUR replied: Yes, Sir.

Hypodermic Syringes for Panel Patients.

Dr. O'DONOVAN asked the Minister of Health what were the regulations governing the prescription and supply of hypodermic syringes to patients suffering from asthma under the care of practitioners on the panel and needing such syringes for self-treatment.—Sir E. HILTON YOUNG replied: The appliances in question are not included in the list of appliances contained in the Second Schedule to the Medical Benefit Consolidated Regulations, 1928, and cannot, therefore, be supplied as part of medical benefit.[1]

TUESDAY, MARCH 8TH.

Pithead Baths.

Mr. PRICE asked the Secretary for Mines the number of coal-mines furnished with pithead baths in each mining area of England, Scotland, and Wales; and the number of cases in which these had been provided out of the Miners' Welfare Fund.—Mr. ISAAC FOOT replied: The total number of coal-mines in England, Scotland, and Wales furnished with pithead baths for workmen is 103. Of these baths, 85 were provided out of the Miners' Welfare Fund, and six were partially paid for by the Fund. In addition, 41 installations, all provided out of the Fund, are in course of construction.

---

[1] See THE LANCET, Feb. 20th, p. 421.

HAMPSHIRE HOSPITALS.—According to the annual report of the Royal Hampshire County Hospital there were last year 2627 in-patients, an increase of 224; 2001 of them were operated upon. They were thus distributed: men, 732; women, 1072; children, 823. There were 6220 out-patients, an increase of 184, of whom 768 were operated upon. The total average cost of each patient has fallen from £9 3*s.* 3*d.* to £8 4*s.* 8*d.*—The Royal South Hants and Southampton Hospital last year reduced the weekly cost per patient from £2 18*s.* to £2 16*s.* 4*d.* The overdraft of £59,000 has been reduced to £18,000 by the sale of securities.

DIFFICULTIES OF NOTIFICATION.

Captain **FRASER** said that the House ought to be sure that the provisions of this Bill were workable. There were various forms of food-poisoning. There was botulism, a very rare form, and one hardly contemplated by the provisions of the Bill. Then there were those forms of poisoning due to poisonous substances being added to food, either for the purpose of preserving the food, and which in excess became poisonous, or which were due to accident. Many cases of so-called food-poisoning arose from these causes, but they were all very slight. The inspectors or medical men would be going on an entirely blank trail if they made any inquiries about them. Then there was the commonest form of food-poisoning at which this Bill doubtless was directed, which was produced by the Gaertner bacillus. That particular bacillus existed in clean as well as in dirty surroundings. The mere removal of dirty surroundings would not remove the possibility or probability of the bacillus being present. It was present in certain kinds of meat and in rodents. It was also present in human beings. It poisoned immediately because the bacillus had put poison into the tissue of the meat, and the poison entered into the human being who had absorbed it. No inspector could find that out by mere insistance on cleanliness. Moreover, there were persons who were carriers of this particular bacillus. They became immune, but they could transmit the bacillus to any food they touched. This Bill would not do what was claimed for it. In the first place it would involve too great an expense, and the community could not afford what might have been desirable two or three years ago; secondly, there was no proof that it would be of the slightest use; and thirdly, there had not been time over a wide enough area for full criticism and complaint to have come forward. Never before had a medical man been asked to notify a disease which was so ill-defined as food-poisoning. He did not think that the mere patching up of these clauses in Committee would meet the case. On every ground Clause 18 ought to be withdrawn. The L.C.C. in the defence of their proposals told them that there were 11 deaths in three years. Yet this vast machinery was to be set up to prevent the recurrence of those cases. He would not mind expenditure to save life, but the accumulation of this kind of expenditure threatened life by making life intolerable for the people. The London County Council could get their Bill through swiftly if they would leave out the offending clauses.

MUCH UNCLEANLINESS.

Mr. **LOGAN** said he knew the benefits from a sanitary point of view which had been derived in Liverpool from registration under the Public Health Act. Had it ever occurred to hon. Members how much uncleanliness there could be in a great city like London in the production of ice-cream and foodstuffs? They allowed health visitors to see if houses were kept clean and not overcrowded, and yet if one bought an ice-cream in London they were not able to tell the purchaser whether it was made in a stable or in a palace. He thought that the London County Council and the sanitary authorities of London were perfectly justified from the point of view of public health in asking for these powers.

Mr. G. **HARVEY** said that in view of the desire of the Minister of Health that the matters raised in the debate should be thrashed out in Committee, and in view of the desire of those who objected to certain clauses of the Bill not to hamper in any way reasonable operations on the part of the L.C.C., he asked leave to withdraw his motion for rejection.

The amendment was withdrawn, and the Bill was read a second time.

VETERINARY SURGEONS BILL.

On Friday, March 4th, in the House of Commons, the Veterinary Surgeons (Irish Free State Agreement) Bill, which has already passed through the House of Lords, was read a second time.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 2ND.

Health Insurance Expenditure.

Mr. **BUCHANAN** asked the Minister of Health the number of persons weekly receiving health insurance benefit, and if the amount was showing an increase or a decrease since the issue of leaflets and instructions to approved societies doctors, and burgh insurance committees at the end of 1929.—Mr. **ERNEST BROWN** (Parliamentary Secretary to the Ministry of Health) replied: The rate of expenditure shows a decrease, and it may be inferred that there is also a decrease in the numbers.

Mr. **BUCHANAN** asked if the hon. gentleman could state the actual decrease.

Mr. **BROWN**: The decrease in numbers could not be stated without examining the records of nearly 8000 approved societies. As regards the amount, the figures will be available in July when the report is published.

Sir P. **HARRIS**: Does this mean that there has been general improvement i

Mr. **BROWN**: I shou

Mr. **BUCHANAN**: Is the decrease the result of the [illegible] circular, or are there other factors; and is not a decrease contrary to what would be expected, seeing that when unemployment is great sickness usually increases?

Mr. **BROWN**: The hon. Member would be unwise to draw the conclusion that the circular is the only factor to be considered.

West Middlesex Sewage Scheme.

Mr. *McENTEE* asked the Minister of Health if it was at the request of the Ministry that the West Middlesex sewage scheme had been suspended; and whether, having regard to the need for this scheme and the number of persons who would be employed, he would urge the Middlesex County Council to proceed with the undertaking.—Sir E. **HILTON YOUNG** replied: I am informed that the West Middlesex sewage scheme has not been suspended. Nine contracts of a total value of well over 1¼ million pounds, have been entered into by the county council, six of which are in active operation. Not less than 725 men are already employed on the scheme.

THURSDAY, MARCH 3RD.

Bread Prices.

Mr. D. **FOOT** asked the Minister of Labour the present comparative price of the 4 lb. wheaten loaf in the following countries: Great Britain, France, Germany, Belgium, Austria, Czechoslovakia, the United States of America, Canada, Australia, Ireland, South Africa, Norway, and Sweden.—*Sir H. BETTERTON* (Minister of Labour) replied: The latest figures available as to the average prices of white bread in the countries named are given in the Table. In the absence of information concerning the qualities of bread to which the various quotations relate, it is not known how far the prices shown may be regarded as comparable one with another.

Country.	Date.	Average price per 4 lb. of white bread.
Great Britain and Northern Ireland (general average) ..	Feb. 1st, 1932.	7*d.*
France (Paris)	January, 1932.	4·09 francs
Germany (6 large towns)	„ 1931.	1·49 reichsmarks.
Belgium (Brussels) ..	„ 1931.	3·16 francs.
Austria (Vienna) ..	Middle of January, 1932.	2·82 schillings.
Czechoslovakia (general average)	December, 1931.	4·2 korunas.
United States of America (51 towns)	Dec. 15th, 1931.	28 8 cents.
Canada (69 towns) ..	Beginning of December, 1931.	24 cents.
Australia (6 large towns)	Sept. 15th, 1931.	7·2*d.* to 10 9*d.*
Irish Free State (general average).	Middle of November, 1931.	8*d.*
Union of South Africa (9 towns)	December, 1931.	14·72*d.*
Norway (general average)	November, 1931.	1·25 kroner.
Sweden (49 towns) ..	January, 1932.	1·35 kroner.

Note.—The figures given are taken from official publications of the countries concerned, except in the case of Germany and Belgium, for which countries they are extracted from the "International Labour Review," published by the International Labour Office, which is the only available source of information as to the price of white bread in those countries.

Imported Milk and Public Health.

Mr. **KIMBALL** asked the Minister of Health whether any action had been taken to discover if fresh milk imported

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

ULMONARY TUBERCULOSIS: AN END-RESULT.

his annual report Dr. William Munro, superin- nt of Glenlomond Sanatorium, makes a very atic statement on the "lateness" of pulmonary culosis. For several years he has been making vations on this problem, which is undergoing ssion everywhere. He states that pulmonary culosis is an end-result, a late visceral manifesta- of a previous infection.

ome medical observers seem to have difficulty in ting this truth. London observers do not appear to l pulmonary tuberculosis as a late manifestation of a ood infection. They are wrong and far wrong. acts are all against them. They point out that in ing the histories of their adult pulmonary cases, they been struck with the fact that few of them ever had nent for any tuberculosis condition in earlier years. cannot have searched the histories very well. They systematic disturbance of a primary infection."

Munro states that he has pleaded for an nination of school-children to determine the ber of reactors, and at leaving that knowledge ld be priceless. From the knowledge supplied routine test one could be on guard every time. her spreads of tuberculosis could be correctly aised and steps taken towards complete arrest he disease in the earliest manifestations. Need- to say, this view is not universally accepted. this time, the data for a final decision should be cient.

DIPHTHERIA IMMUNISATION.

n the London County Council report on diphtheria. nburgh, Aberdeen, Dundee, and Glasgow get credit for their pioneer work in this field. erdeen and Edinburgh stand easily first. It is icult to understand why either Scotland or England been so slow to develop the Schick test and oid immunisation as well as scarlet fever immunisa- n. But the amount actually accomplished in otland has, on the whole, been very satisfactory. Aberdeen, Dundee, and Edinburgh the parents ame enthusiastic.

MEDICAL NEWS

iversity of London.

The University Court has accepted a gift of £88,000 m the Rockefeller Foundation towards the endowment the department of zoology and comparative anatomy University College. The gift was conditional, inter alia, the University providing £30,000 for land, buildings, d equipment, and this condition has now been met.

The Senate has approved in principle the institution of Academic Diploma in Radiology, and syllabuses therefore ll be issued in due course.

Sir Ernest Graham-Little, M.P., has been appointed a ember of the court of governors of the London School of giene and Tropical Medicine, and Sir William Collins ll represent the University at the tercentenary celebrations the University of Amsterdam next June.

The Senate will shortly consider applications for grants rom the Dixon Fund for assisting scientific investigations, nd for the Thomas Smythe Hughes and Beaverbrook dical Research Funds for assisting original medical search. Applications must be received in proper form not later than May 15th. Application is also invited for the Laura de Saliceto Studentship for the advancement of Cancer Research, which is of the value of £150 a year. Candidates may be of either sex and need not be members of the University. Further particulars may be had from the Academic Registrar.

International Society of Orthopædic Surgery.

The second congress of this society will be held in London at the house of the Royal Society of Medicine from July 19th to 22nd, 1933, under the presidency of Prof. Nové-Josserand, of Lyon.

Territorial Army Medical Officers' Association.

A general meeting of this association will be held at 37, Russell-square, London, W.C., on Thursday, March 17th, at 3 P.M., at which all Territorial Army medical officers (active and retired) are invited to be present.

Lectures on Tropical Hygiene.

The British Red Cross Society will hold a course of seven lectures and demonstrations on tropical hygiene at 5.30 P.M. on Mondays, Wednesdays, and Fridays, from April 4th, at 9, Chesham-street, London, S.W.

Royal Medical Benevolent Fund.

The ninety-sixth annual general meeting of this Fund will be held in the rooms of the Medical Society of London, 11, Chandos-street, W., at 5 P.M., on Tuesday, March 15th.

Radium Institute, London.

Lord Moynihan, of Leeds, has been elected a member of the committee of this Institute in the place of Sir Hugh Rigby, who has resigned.

Sheffield Hospitals' Contributory Fund.

Last year this fund collected £103,861, a decrease of £7585; but 32,000 contributors have promised to increase their weekly payments from 1d. to 2d. in the pound, which will add £9500 to the annual income.

Nottingham General Hospital.

Mr. R. G. Hogarth, senior surgeon of Nottingham General Hospital, recently reopened the old main theatre of the institution which has been reconditioned at a cost of £4000, given by Sir Thomas Shipstone. It will in future be known as the Shipstone theatre.

Enlargement of Weymouth Hospital.

The Earl of Shaftesbury, Lord-Lieutenant of Dorset, has opened an extension of Weymouth and District Hospital which has cost £15,000. The additions comprise a large waiting-room, a new dispensary, a casualty room adjoining the main entrance, a new theatre, four doctors' consulting rooms, a dental surgery, ear, nose, and throat, electrical and massage departments, and an extension of the X ray room.

Society of Public Analysts.

The fifty-sixth anniversary dinner was held on March 4th at the Trocadero, when the chair was taken by the retiring President, Mr. J. T. Dunn, public analyst for Newcastle-on-Tyne. The President-elect, Mr. F. W. F. Arnaud, occupied the vice-chair. Among the guests were Lord Atkin, who proposed the toast of the Society; the Lord Mayor of Newcastle, the President of the Royal Society, Sir Ernley Blackwell, and Sir Ernest Graham-Little. In replying to the toast of the Civil Service, Sir E. Blackwell referred to the appointment of two early members of the Society, Sir Thomas Stevenson and Dr. C. Meymott Tidy, as the first Home Office analysts, and remarked that the findings of fact by the official analyst were invariably accepted by the other side in court, although alternative explanations were frequently offered. Lord Atkin referred to his experiences of the working of the Food and Drugs Act as a member of a county bench in Wales. He stressed the importance of adequate standards, not only for milk, but for any other foods to which they might be applicable. He quoted Tennyson's lines (from Maud) written at a time (1855) when public opinion on the adulteration of foods and drugs was becoming ripe for legislation—

"... chalk and alum and plaster are sold to the poor for bread,
And the spirit of murder works in the very means of life."

and

"... another is cheating the sick of a few last gasps, as he sits
To pestle a poisoned poison behind his crimson lights."

Sir Gowland Hopkins, in responding for the Kindred Societies (proposed by Mr. A. Chaston Chapman, F.R.S., a past President) which were also represented by Prof. G. T. Morgan (President of the Society of Chemical Industry), Mr. Percy Gates (President of the Institute of Brewing), Mr. George Gray (Vice-President of the Institute of Chemical Engineers), by the Registrar, Mr. R. B. Pilcher, and many Fellows of the Institute of Chemistry, referred to his early days as an articled pupil of a public analyst.

OBITUARY

ARTHUR BOULTON, M.R.C.S. Eng., D.P.H.

Dr. Boulton, who died on Feb. 15th at the age of 65, was the son of the late Dr. A. E. Boulton, of Horncastle. Educated at Epsom College, he studied medicine at Charing Cross Hospital, and took the conjoint diploma in 1890. A few years later he obtained the D.P.H., having in the meantime acted as surgeon to the Cornelia Hospital at Poole, surgeon to the Clan Line, while for a time he was assistant visiting surgeon to the Albany General Hospital, Grahamstown, S. Africa. On returning to England he became M.O.H. to the Horncastle rural and urban district councils and to the Woodhall Spa urban district council. He was inspector for epileptic and mentally defective children to the Lindsay Educational Committee, medical superintendent of the isolation hospital, medical officer to the Horncastle Dispensary, and medical referee to several insurance companies. In his early days Dr. Boulton had been a keen sportsman and a good footballer, while he was an accomplished amateur actor.

BOSTON ELPHINSTONE FORDYCE, M.B. Edin.

Dr. Fordyce, who died at a nursing home in Cambridge on Feb. 19th at the age of 74, was a well-known medical man in the city, having been in practice there for more than 40 years. Born at Duns, Berwickshire, in 1858, he graduated in medicine and surgery at Edinburgh in 1883. Early in his professional life he came to Cambridge, and soon acquired a considerable practice. He was an active member of the British Medical Association, on which body he represented East Anglia, while he also interested himself in public affairs, and became a member of the Cambridge county council in 1895. He was made an alderman in 1913, the year before he resigned from the council, and during the 19 years of his municipal service he did useful work on public health and education committees. In 1922 he became a member of the Cambridge town council, representing West Chesterton ward till 1926, and interested himself in public health and maternity and child-welfare work. He married Mabel, youngest daughter of the late Dr. William Moxon, of Northampton, and leaves two daughters and one son.

Dr. Robert Emmerson Brown, who died at Willington, Co. Durham, at the age of 67, was a popular practitioner and a prominent Freemason. He retired from practice last year. Qualifying with the Scottish triple qualification in 1890, Dr. Brown set up in practice at Willington, and met with professional success at once. He was appointed medical officer of health to the urban council, and held the post for 40 years; also a similar office for the western district of the Durham union for 30 years. His other public appointments included those of colliery surgeon for the Brancepeth group of collieries, police surgeon, and railway surgeon. He leaves a widow and a son, Dr. R. A. Brown, who has assisted his father for some years.

Dr. Oliver Barber, whose death took place on Feb. 14th at St. Leonards, Sussex, was in practice for more than half a century there and in Sheffield. He was born in Yorkshire, and qualified in 1872 with the usual diploma, and after holding a resident post at the South Staffordshire Hospital, Wolverhampton, became resident surgeon at the Sheffield Royal Infirmary, and demonstrator of anatomy at the School of Medicine, now a department of the University of Sheffield. On retiring from this post he graduated M.D. at St. Andrews in 1892 and joined his brother in Sheffield in private practice, but a severe illness in 1896 caused him to seek the climate of Hastings, where he remained until his death, and in active practice until 1919. During the war he was examiner for recruits for the Hastings district, a duty which he discharged with efficiency.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

The following appointments have been notified: Surg. Comdr. J. D. Bangay to *Victory*, for R.N. Barracks.

Surg. Lts. W. D. M. Sim to *Pembroke*, for R.N. Barracks and W. V. Beach to *Delhi* and to *Dragon*.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Sub-Lt. A. C. Howard to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

The notification of the relinquishment of the prov. rank of Capt. by Lt. (prov. Capt.) J. W. Kendall, half-pay list, is cancelled.

Lt. (on prob.) R. C. Langford is restd. to the estab.

Lt. W. D. Hughes to be Capt.

The undermentioned to be Lts.: C. S. Gross and D. P. F. Mulvany, from temp. commns.

T. J. Moloney is granted a temp. commn. in the rank of Lt.

TERRITORIAL ARMY.

Col. Sir W. R. Smith vacates the appt. of Hon. Col. R.A.M.C., Units, 44th (Home Counties) Div. T.A., on completion of tenure.

Col. C. P. Oliver (late R.A.M.C., T.A.) to be Hon. Col. R.A.M.C., Units, 44th (Home Counties) Div. T.A.

Col. J. Clay vacates the appt. of Hon. Col. R.A.M.C., Units, 50th (Northumbrian) Div., T.A., on completion of tenure.

Col. J. M. Gover to be Hon. Col. R.A.M.C., Units, 50th (Northumbrian) Div., T.A.

DEATHS IN THE SERVICES.

Lt.-Col. James Henry Reynolds, A.D.M.S. (retd.), V.C., who died at the age of 88 on March 4th, was the son of Mr. L. Reynolds, J.P., of Co. Longford, and was born at Kingstown in 1844. He graduated in medicine and surgery at Trinity College, Dublin, in 1867, and received his first commission in the Army in the following year. In 1875 he accompanied the expedition to Griqualand, and afterwards distinguished himself in the South African operations of 1877–79, serving in the Kaffir campaign and the Zulu campaign, and being present at the Defence of Rorke's Drift and at the battle of Ulundi. It was at Rorke's Drift that he won the V.C., the official record being "for the conspicuous bravery during the attack at Rorke's Drift on Jan. 22nd and 23rd, 1879, which he exhibited in his constant attention to the wounded under fire, and in his voluntarily conveying ammunition from the store to the defenders of the hospital, whereby he exposed himself to a crossfire from the enemy both in going and returning." Mentioned in despatches, he also received the medal with clasp, and was specially promoted Surg.-Major. He was awarded the Gold Medal of the British Medical Association, elected an honorary Fellow of the Royal College of Physicians of Ireland, and made an honorary LL.D. of Dublin. Lt.-Col. Reynolds married in 1880 Elizabeth, daughter of Dr. McCormick. He retired in 1896.

It will be recalled that Lt.-Col. Reynolds was one of the seniors among the distinguished company who attended the dinner to V.C.'s, over which the Prince of Wales presided at the House of Lords in 1929.

Lewes Hospital Penny Fund.—In the eight years of its working £6950 has been raised by this Fund; £6491 has been paid to the Lewes Victoria Hospital and £353 to other institutions. The total cost of administration in the eight years has been only £106.

2 P.M. to 4 P.M., Operations, Medical, Surgical, and Throat, Nose and Ear Out-patients.

URDAY.—9 A.M. to 1 P.M., Throat Operations, Medical Ward Visit. Children's Medical Out-patients. Surgical Out-patients.

I-WEST LONDON POST-GRADUATE ASSOCIA-, St. James' Hospital, Ouseley-road, Balham.

TESDAY, March 17th.—4 P.M., Dr. Hector C. Cameron: Demonstration of Children's Ailments.

NAL HOSPITAL, Queen-square, W.C.

NDAY, March 14th.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Hinds Howell: Trauma in Relation to Nervous Disorders.

ESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Adie: Neurosyphilis.

EDNESDAY.—2 P.M., Dr. Martin: Out-patient Clinic.

URSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Mr. Just: Intracranial Complications of Otitis Media.

IDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. James Collier: Remarks upon *Polyneuritis*.

ING CROSS HOSPITAL MEDICAL SCHOOL.

NDAY, March 13th.—10.45 A.M., Dr. C. K. H. Hamilton: The Premature Infant. 11.45 A.M., Mr. A. C. MacLeod: Radium Therapy from the Clinical Aspect.

S COLLEGE HOSPITAL MEDICAL SCHOOL, mark-hill, S.E.

HURSDAY, March 17th.—9 P.M., Mr. W. I. Daggett: Ear, Nose, and Throat Operations of General Practice.

L NORTHERN HOSPITAL, Holloway-road, N.

EDNESDAY, March 16th.—3.15 P.M. (at the Royal Chest Hospital), Dr. P. Kerley: Radiological Examination of Cardiac Cases.

ARK'S HOSPITAL, City-road, E.C.

HURSDAY, March 17th.—4.30 P.M., Mr. W. B. Gabriel: The Elucidation of Rectal Symptoms; Pain.

RAL LONDON THROAT, NOSE, AND EAR HOS-AL, Gray's Inn-road, W.C.

RIDAY, March 18th.—4 P.M., Mr. J. D. McLaggan: Giddiness.

PSTEAD GENERAL AND NORTH-WEST LONDON SPITAL.

VEDNESDAY, March 16th.—4 P.M., Dr. H. C. Semon: Diseases of the Buccal Mucosa.

DON SCHOOL OF DERMATOLOGY, St. John's Hospital, Leicester-square, W.C.

UESDAY, March 15th.—5 P.M., Dr. H. MacCormac: Malignant Growths of the Skin.

THURSDAY.—5 P.M., Dr. I. Muende: Pathology Demonstration.

IONAL COUNCIL FOR MENTAL HYGIENE.

WEDNESDAY, March 16th.—5.30 P.M. (at 11, Chandos-street, W.), Mr. Gerald Heard: Penal Methods of the Future.

OATS HOSPITAL, Manchester.

THURSDAY, March 17th.—4.15 P.M., Miss M. Hilton Royle: The Influence of Body Mechanics on Health. (With Demonstration of Exercises.)

MARY'S HOSPITALS, Manchester.

FRIDAY, March 18th.—4.15 P.M. (at the Whitworth-street West Hospital), Mr. Arnold Jones: Allergic Affections of the Nose and Throat.

CHESTER ROYAL INFIRMARY.

TUESDAY, March 15th.—4.15 P.M., Dr. C. H. Melland: Some Cases of Cardiac Irregularity.

FRIDAY.—4.15 P.M. Dr. A. H. Holmes: Demonstration of Medical Cases.

FORD ROYAL HOSPITAL.

THURSDAY, March 17th.—Mr. G. Jefferson: Demonstration of Surgical Cases.

THALMIC INSTITUTION, Glasgow.

WEDNESDAY, March 16th.—4.15 P.M., Dr. Alex. Garrow: Eye Cases.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Hon. Ophth. S., Cas. O. £200. Also H.S. At rate of £100.

St. Alfege's Hospital, 48, Vanbrugh Hill, Greenwich, S.E.—Res. Asst. M.O. £350.

St. Helens County Borough.—Deputy M.O.H. £700.

St. Leonards-on-Sea, Buchanan Hospital.—Jun. H.S. At rate of £125.

St. Thomas's Hospital.—Ophth. Reg. and Refractionist. £200.

Salford, Hope Hospital, Pendleton.—Asst. Res. M.O. At rate of £250.

Salford Royal Hospital.—Hon. Physician.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—Anæsthetist.

Scarborough Hospital and Dispensary.—Two H.S.'s. Each at rate of £175.

South London Hospital for Women, Clapham Common, S.W.—H.P. and two H.S.'s. Each at rate of £100.

Southampton, Royal South Hants and Southampton Hospital.—Hon. Asst. Surg.

Southend-on-Sea, New General Hospital.—Hon. Surgeon, Physicians, &c. Pathologist £500. Radiologist £500, and Pharmacist £350.

Stafford, Staffordshire General Infirmary.—H.P. At rate of £150.

Stoke-on- [illegible] *ry.*—H.S. £150.

Taunton, [illegible] House M.O. and H.S.

Victoria [illegible] *Chelsea, S.W.*—Dental Surgeon.

Wakefield Clayton Hospital.—Two Jun. H.S.'s. Each at rate of £150.

West London Hospital, Hammersmith-road, W.—H.P. and H.S.'s., H.S. to Ear, Nose, and Throat Dept., and Res. Anæsthetist. Each at rate of £100. Also Hon. Med. Radiologist.

Wigan, Royal Albert Edward Infirmary and Dispensary.—H.S. At rate of £150.

Willesden General Hospital, N.W.—Cas. O. At rate of £120. Also H.S. and H.P. At rate of £110 and £100 respectively.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Esher (Surrey), and Leamington (Warwick).

CORRECTION.—In the report last week (p. 514) of the Section of Comparative Medicine at the Royal Society of Medicine the remarks on milk fever and eclampsia attributed to Prof. F. J. Browne were made by Mr. R. H. Paramore.

King Edward's Hospital Fund for London.

Hospitals within 11 miles of St. Paul's desiring to participate in the grants made by King Edward's Hospital Fund for London for the year 1932 must make application before March 31st to the hon. secretaries of the Fund at 7, Walbrook, E.C. 4. Applications will also be considered from convalescent homes which are situated within the above area or which take a large proportion of patients from London.

Victor Horsley Memorial Lecture.

The Victor Horsley Memorial Fund was raised in 1920 to commemorate the services of Sir Victor Horsley to science and the Empire, and is devoted to the giving of a lecture triennially in London entitled the Victor Horsley Memorial Lecture. The fourth lecture is due to be delivered in 1932, and the trustees (who consist of the Presidents of the Royal Society, the Royal College of Surgeons of England, and the British Medical Association, the senior physician of the National Hospital for the Paralysed and Epileptic, Queen-square, the senior surgeon of University College Hospital, and Mr. Stanley G. Robinson, the son-in-law of Sir Victor Horsley) have invited Prof. E. D. Adrian, F.R.S., F.R.C.P., of Cambridge, to give the lecture. This he has consented to do, and the lecture will be delivered on July 20th next, under the title of Visceral Sense Organs. It is hoped that Sir Frederick Gowland Hopkins, F.R.C.P. (President of the Royal Society), will take the chair, and further details will be published later.

Contributory Patients and Medical Staffs.

Last year the Pembrokeshire County War Memorial Hospital admitted the record number of 862 in-patients, and the annual report expresses the hope that "at some future time, when money permits," it may be further extended. The report of the medical staff contends that this time has come, since the hospital is "in a happy and unusual financial position," and calls attention to "the total inadequacy of accommodation and resulting overcrowding of patients in the wards," which results almost entirely from emergency admissions. The present situation is "totally unacceptable to the visiting staff." Last year's income was increased from just over £7000 to just under £8000, mainly on account of the "extraordinary measure of popularity" of the contributory scheme. The medical staff think that there should be more efficient control over the eligibility for treatment of patients under that scheme. They suggest the appointment of a reception committee "with a due representation of the medical staff." The medical fund received £958, at the rate of £2 3s. 3d. for every contributory patient.

ADDRESSES AND ORIGINAL ARTICLES

THE PATHOLOGY AND TREATMENT OF ANÆMIA.

BY L. J. WITTS, M.D. MANCH., F.R.C.P. LOND.,
SISTANT PHYSICIAN TO GUY'S HOSPITAL; WILL EDMONDS CLINICAL RESEARCH FELLOW.

LECTURE III.

THE HÆMOLYTIC ANÆMIAS.*

> "A man's index of scepticism must indeed be low if he can believe that these terrible, acute anæmias are the result of chronic foci of infection in teeth or tonsils, and can bring himself to hope for relief from their eradication."
>
> R. C. LARRABEE.

ANÆMIA from hæmolysis or increased destruction f red corpuscles is uncommon. It presents problems f great difficulty. Cases are rare, and in the published eports essential details and investigations are lacking. knowledge that powerful hæmolysins can be elabrated by bacteria has prejudiced the approach to the roblem and prevented the orderly accumulation of acts. A natural confusion with anhæmopoietic næmias such as pernicious anæmia has been a further ar to progress. I propose first to discuss briefly hæmolytic anæmias whose pathology is understood. Afterwards, in the light of the knowledge acquired rom these anæmias and from our previous study of the erythron and its diseases, it may be possible or us to discern some unifying or distinguishing eatures in the hæmolytic anæmias of unknown origin which remain for consideration.

The most important group of hæmolytic anæmias s constituted by those of congenital or familial origin: acholuric family jaundice, sickle-cell anæmia, the erythroblastic anæmia of infants, and icterus gravis neonatorum. For information about acholuric jaundice I am fortunate in being able to refer you to our President's comprehensive studies.[15] Acholuric jaundice and sickle-cell anæmia are dependent on the presence of an abnormal type of corpuscle, which is ill-adapted to life in the blood stream, but the factors which determine the degree and the variations in hæmolysis are obscure. The pathology of the erythroblastic anæmia of infants is unknown.[77] Icterus gravis neonatorum is a most interesting disease, which may shed light on the mechanism of the acute anæmic breakdowns of later life and which therefore deserves rather longer mention. In this grave familial jaundice, successive infants in a family become jaundiced a few hours to a day after birth. They become progressively anæmic, pass into a drowsy condition, and usually die in a few days or weeks. The disease resembles physiological jaundice in its onset, and, like it, it does not show any gross post-mortem appearances to account for the jaundice.[61] During intra-uterine life the red cells circulate in higher concentration than after birth to compensate for the poor supply of oxygen from the placenta. It is probable that physiological jaundice results from the hæmolysis of superfluous corpuscles on the adoption of pulmonary respiration, and that grave familial jaundice is a morbid exaggeration of this process. Affected children nearly always died till Hampson showed that they could be cured by the injection of normal human serum, and that after this they developed normally. This is a close parallel to the striking effects of transfusion in the acute anæmic breakdowns of later life. In conclusion, we may observe that liver is of little or no value in any of these familial hæmolytic anæmias. The decrease in hæmolysis and the improvement in the patient which follows splenectomy in acholuric jaundice are well known. Unfortunately this operation seems to be of no such constant assistance in sickle-cell anæmia or in the erythroblastic anæmia of infants.

CAUSES OF HÆMOLYTIC ANÆMIA.

Hæmolytic anæmia may be the result of a variety of infections[39] and organic or inorganic poisons. It is exceedingly uncommon for the ordinary streptococci to cause a hæmolytic anæmia; anaerobic streptococci, such as are often responsible for puerperal fever, are more potent, but the organism which stands out above all others is *Bacillus welchii.* In gas gangrene profound anæmia may develop in a few days or hours, the red cells are destroyed so rapidly that hæmoglobin and its derivatives may appear in the urine, there is frank jaundice, the white cells are increased to 50,000 or more, and myelocytes appear in the blood. In the effort to repair this sudden destruction of red cells, erythroblasts of the most primitive type are poured into the blood stream and there is a great reticulocytosis. Recovery is rapid and spontaneous if the infection is overcome. In these anæmias from infection, there is rarely any doubt about the presence of a gross infection and the organisms can be cultivated from the blood. It must be remembered that anæmic patients are very unresistant to infection, especially by streptococci, and many mistakes have been made in attributing anæmia to infection, when a more careful history would have shown that the infection was the complication or termination of a pre-existent idiopathic anæmia.

Hæmolytic anæmia has been described in typhoid fever,[36 66] disappearing when the disease was cured, but here there is the possibility that the condition was an Addisonian anæmia due to the disease of the alimentary tract and not a hæmolysis. There is, however, one infection both in man and animals, of which the most characteristic feature is a hæmolytic anæmia. In bartonella infection,[70] which in man is known as Oroya fever, the red cells are invaded by the organisms and broken up, often with resultant hæmoglobinuria and jaundice. A profound anæmia of a megalocytic type soon develops, and again there is a leucocytosis and the outpouring of immature red and white cells from the marrow. We must all agree that these hæmolytic anæmias, in which the red cells are destroyed by the direct action of organisms or their poisons, are extremely uncommon except for gas gangrene and puerperal fever. Equally uncommon is hæmolysis by the direct action of poisons such as the aniline derivatives, though it may occur in industrial accidents and in suicides, and it is identical with the effects of bacterial hæmolysins.

More frequent are the hæmolytic anæmias which appear to be the result of an infection or harmful agency, such as the paroxysmal hæmoglobinuria of syphilis and the blackwater fever of malaria. Here the infecting organism does not act directly on the red cells, but apparently produces a

Notes, Comments, and Abstracts

PROSTATIC CALCULI.

J. A. Lazarus and A. A. Rossenthal,[1] of New York state that 370 cases of prostatic calculi have been reported, although many more are encountered than are published. Until the introduction of radiography in routine urological examinations prostatic calculi were supposed to be rare, but modern methods of exploration have shown that they are not uncommon. As regards their ætiology the writers hold that calculi of the prostate, like those found elsewhere in the body, are due to a variety of causes. As a rule a pre-existing infection of the gland in a man with a tendency to calcium deposition seems to be the most likely explanation of calculus formation. The calculi vary in size, consistence, and chemical composition. The nucleus usually consists of epithelial debris, blood clot, bacteria, corpora amylacea, or necrotic tissue, and the surrounding layers are made up of calcium phosphate, calcium carbonate, calcium oxalate, and ammonio-magnesium phosphate. Most prostatic calculi are found in the lateral lobes, *and the median lobe is an occasional site*, but the anterior and posterior lobes are rarely, if ever, involved. The calculi are usually multiple, but 33 cases are on record in which only a single stone was found. Most of the cases occur after puberty, the majority being found in the fifth decade, and two-thirds of all the cases in the fourth, fifth, and sixth decades. In the writers' series of 15 cases the youngest patient was 28 and the oldest 75. In many cases prostatic calculi give rise to no symptoms but are accidentally discovered in a routine urological examination by X rays and rectal exploration. In a fair number however the following symptoms are met with in order of frequency: diurnal and nocturnal pollakiuria, dysuria, perineal, penile, and rectal pain, urgency and tenesmus, hæmaturia, retention, impotence, and hæmatospermia. The diagnosis is established by rectal examination and X rays. Prostatic calculi must be distinguished from chronic prostatitis, with hard, nodular, inflammatory, or malignant infiltration, or tuberculosis of the prostate. Complete recovery follows removal of the calculi. If the condition is left untreated, abscess formation, cystic degeneration, gangrene, or carcinoma may result. Suprapubic prostatectomy in two stages is regarded as the operation of choice, but if no symptoms are present, diathermy followed by massage of the prostate is sufficient.

AËDES EGYPTI AT BAKU.

How clever are female mosquitoes at finding safe and secret places for their eggs. *Aëdes egypti* (formerly called *Stegomyia fasciata*), which lives about human dwellings, affords an example. It has been widely reported from the Black Sea coast, but only now[2] from the Caspian, by Dr. I. Achundow, entomologist to the Baku Tropical Disease Institute, who was anxious to determine if this yellow fever carrier occurred in his area. He was lucky when a female flew into his room last July and, being caught, laid 30 eggs from which in ten days—temperature of the aquarium water 77° F.—there developed two male and three female undoubted *Aëdes egypti* imagos. About this time, as he was calling on a relative who lived in the centre of the town, Dr. Achundow was bitten by an aëdes, and, as mosquitoes were said to be a plague in that flat, though on the third floor, search was made, and in the back kitchen, under a pile of wood fuel, was found a wooden washing tub (a quarter full of water to keep it from warping) teeming with aëdes larvæ. A similar finding was made in other neighbouring flats. They do their washing in Baku every two or three weeks, and the mosquitoes have double that time if the family is holiday.

Thus we see how thoroughly mosquito inspectors must know the customs of the people they are protecting. Who would have expected to find a mosquito breeding place on a third floor? Another thought: how many vain journeys a pregnant aëdes must have made to the woodpile before she found the family wash was over and the tub, with its welcome water content, returned into store!

PHYSICAL EXERCISES FOR THE MIDDLE-AGED

THE indiscriminate daily practice of physica exercises by the middle-aged does not always have favourable effect on general condition, and ma certainly do harm if the exercises are such as t cause undue strain. Many modern gymnastic however, can be adapted for older people, an graduated training in suitable physical exercise undoubtedly makes for general wellbeing. Mi M. H. Spalding, late vice-principal of the Bergma Österberg Physical Training College, has started sma classes for physical culture at 105A, Gloucester-road London, S.W.7, which are specially arranged fo women who have few, if any, facilities for game or sports, and *have difficulty in securing* regula exercise. Separate classes for men are also organise The scheme of exercises is based on the preventiv rather than the curative aspect of physical culture.

Appointments

ABERNETHY, W. R., M.B., B.Ch. Belf., D.P.H., has be appointed Superintendent M.O.H., Executive Sanita Officer, Schools Medical Officer, and Tuberculosis Offic of Derry.

PADDINGTO HOSPITAL: Mr. DUNC C. L. M.D., F.R.C.S., Consu ing Su ; Mr. BERTRAM SAMU L.D.S. R.C.S., Consulting Dental Surgeon to the Hospita Mr. C. E. SHATTOCK, M.D., M.S., F.R.C.S., Surgeon in charge of In-patients; Mr. F. W. M. PRATT, M.B., B. F.R.C.S., Honorary Surgeon to Out-patients; and Mr. H PITT, L.D.S. R.C.S., Honorary Dental Surgeon.

Certifying Surgeons under the Factory and Workshop Ac

Hogben, G. H., L.R.C.P. Lond., M.R.C.S. (Swinton, Lancs

Murray, J. D., M.B. Ch.B. Aberd. (Grays, Essex).

Births, Marriages, and Deaths

BIRTHS.

APPLIN.—On March 5th, at Park-lane, Croydon, the wife H. W. Applin, M.B., B.S., M.R.C.S., of a son.

HARKNESS.—On March 7th, at Devonshire-place, W., the w of R. C. Harkness, F.R.C.S., of a daughter.

HUNTER.—On March 2nd, at Lindfield-gardens, N.W., wife of Dr. Donald Hunter, of a daughter.

PALMER.—On Feb. 29th, the wife of Dr. H. M. Palmer, Wealden Stow, Bidborough, Kent, of a daughter.

WAKLEY.—On Feb. 17th, at Playden, Chipstead, Surrey, Daisy (*née* Trist), the wife of Thomas L. Wakley daughter.

MARRIAGES.

HOWAT—RICKETTS.—On March 4th, at Enfield, Clarence H Howat, M.B., Ch.B., to Audrey May Ricketts.

DEATHS.

CAMPBELL.—On March 1st, at Brompton Hospital, London, Dr. R the result of wounds received during the Great War,

GRA Eveline Dorothy (Sister La bery Hill, Birmingham, in 48th year.

HOAR.—On March 6th, at Montcalm, Maidstone, Cha Edward Hoar, M.D. Lond., J.P., in his 85th year.

IRVING.—On Feb. 27th, at Bell-street, Henley, Hamil Irving, M.S., F.R.C.S., of Huddersfield.

MACVICAR.—On Feb. 27th, Acharacle, Arg Dr. Symers Douglas

MORGAN.—On March 2nd, gan, M.R.C L.R.C.P., aged 35.

REYNOLDS.—On March 4th., Lieut.-Colonel J. H. Reynol V.C., late R.A.M.C., aged 88.

SYDENHAM.—On March 7th, at Pitt House, Dawlish, Dev George Mervyn Sydenham, M.D., aged 62.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices Births, Marriages, and Deaths.

s type is premature when knowledge is so imperfect, l Panton showed that iron pigmentation might be efly localised in the skin.

These cases differ from congenital acholuric ndice in the absence of a family history and in the e and shape of their red cells. In acholuric ndice the red cells are small and spherical, while acquired hæmolytic anæmia they are usually a le larger than normal and not spherical (cf. Fig. 2). e fragility may be impaired in both diseases, ough more constantly in acholuric jaundice. pathology these anæmias are obviously quite ferent from pernicious anæmia, being the result increased blood destruction and not of diminished mation. They show some features in common th the hæmolytic crises of late syphilis and malaria, t differ in their persistent hæmolysis. A similar pe of anæmia sometimes occurs in aleukæmic kæmia, and more seldom in Hodgkin's disease. ese comparisons suggest the possibility of morbid anges in the body fluids or the reticulo-endothelial stem. When the spleen is enlarged, benefit may llow its removal but cannot be promised with e same confidence as in acholuric jaundice. Medical eatment is ineffective and transfusion often harmful.

Anæmia in Childhood.

Before discussing the acute hæmolytic anæmias, must make a short digression into the anæmias of fancy and childhood, and here, as my own experience small, I will follow closely Nobécourt's description. he anæmias of infancy and childhood are still nperfectly understood. This is due partly to the ifficulty of investigating these little patients, but ven more to the lability of the erythron at this time f life. Leaving on one side anæmias due to diseases of he liver and spleen, of the white cells, and of the latelets—and in practice it is not always easy to ifferentiate them from diseases of the erythron tself—the pediatrician is accustomed to divide the næmias of infancy and childhood into the mild or *imple*, and the severe or grave. The *simple*, which re usually of a chlorotic type, do not concern us now. The grave anæmias of childhood sometimes date from an acute infection such as measles but just as often there is no apparent cause. They fall into two groups, the aplastic and the plastic; intermediate forms of a hypoplastic type also seem to occur. In the *aplastic anæmia* morphological changes in the red cells are absent, there is little anisocytosis or polychromasia, there are no nucleated red cells, and the white cells are diminished in numbers. The disease undoubtedly corresponds with the aplastic anæmia of later life. Death may occur from the complete failure of the marrow, or, more often than in adults, there is a gradual resumption of function. This aplastic anæmia will not be referred to again. In the *plastic anæmia* of childhood there is much anisocytosis and polychromasia, normoblasts and megaloblasts circulate in the peripheral blood the white cells are much increased in numbers, and large numbers of myelocytes may be present. The spleen may be enlarged and more rarely lymph glands are palpable. This type of anæmia is most common in sucklings, and of 124 cases collected by Hallez (quoted by Nobécourt) 120 were less than 2 years of age and the majority from 6 to 20 months. It is this type of anæmia occurring in infants which is often known as the pseudoleukæmia of von Jaksch, but von Jaksch's syndrome is at present in the melting pot, and I shall therefore make no further reference to anæmia in infancy.

Price-Jones curves in chronic acquired hæmolytic anæmia and in acholuric jaundice.

Acute Hæmolytic Anæmia.

In discussing these plastic anæmias Nobécourt refers to several cases of the same type he has encountered in later childhood and in adults. From a study of the literature and of a series of cases observed by R. J. L. O'Donoghue and myself at Guy's Hospital, I have felt that it will be profitable to collect them together change in the patient's organism, which leads to hæmolysis under special conditions of temperature, medication, and so on. Closely related to these diseases is Fabismus, a hæmolytic anæmia found in Italy, which follows the ingestion of beans (*Vicia faba*) or even the inhalation of their pollen.[60] It is probably due to sensitisation to some constituent of the plant. Nothing happens to the patient on first eating the beans or coming into contact with the plant, but on the second occasion, perhaps months later, there is a rapid hæmolysis of the red cells, often with hæmoglobinuria and always with anæmia. Finally we may mention the hæmolytic anæmia which may develop in man and animals as the result of frequent transfusion with a perfectly compatible blood. An animal so treated learns to dispose of the transfused cells with increasing celerity, and in certain cases the hæmolytic process may not stop at the destruction of the superfluous cells but may progress and produce a severe hæmolytic anæmia.[63]

CHARACTERISTICS OF HÆMOLYTIC ANÆMIA.

We are now in a position to describe the characteristics of a hæmolytic anæmia. It may develop with very great speed and then disappear as soon as the hæmolysed cells can be replaced, or it may be chronic and persistent, or it may run a chronic course with periodic exacerbations. If a great many red cells are broken down in a short time, there are hæmoglobinuria and jaundice, but in chronic hæmolytic anæmia it is sometimes surprising how slight is the jaundice. The colour-index varies according to the mode of reaction of the bone-marrow but it is usually round about unity and there may be frank megalocytosis. Owing to the vigorous attempts of the bone-marrow to repair the anæmia, the reticulocyte count is high, and nucleated red cells and even megaloblasts appear in the peripheral blood. The fragility of the red cells varies in different individuals and at different times in the same individual. The resistance to hypotonic saline may be diminished in acquired hæmolytic anæmia, and it may be normal in congenital acholuric jaundice.[15] In chronic hæmolytic anæmia the white cells are unaffected or a little diminished. When hæmolysis is acute and rapid, there is a leucocytosis during which very immature white cells may appear in the peripheral blood; the platelets first fall and later rise above their normal level. Apart from the hæmolysis, which gives rise to the depressing effects of anæmia, enlargement of the liver, spleen, and occasionally of lymph glands, hyperplasia of the bone-marrow and hæmosiderosis, there are no signs of systemic disease, and the alimentary tract and nervous system are normal. In the ætiology of these anæmias we can distinguish three different kinds of factor: first, a hereditary dystrophy of the erythron; second, immediate destruction of erythrocytes by micro-organisms, toxins, and chemical agencies; third, hæmolysis from morbid changes in the body fluids and the reticulo-endothelial system, which may be the result of infections, poisons, or other agencies.

Chronic Acquired Hæmolytic Anæmia.

I have thought it unwise to attempt any formal classification of the obscure, hæmolytic anæmias which remain to be considered, and I shall merely divide them into two groups. In the first group, which I shall call *chronic acquired hæmolytic anæmia*, the hæmolytic process persists once it has been established, though it is often subject to periodic exacerbations. In the second group, which I shall call *acute hæmolytic anæmia*, the disease is self-limited, and if the patient survives the crisis of the illness, complete recovery occurs in a few months or at any rate within a year. I can best describe chronic acquired hæmolytic anæmia by reporting the following case:—

A woman, aged 20, was admitted to Guy's Hospital on April 18th, 1931. Her illness began suddenly in March, 1929, with the passage of bloody urine, followed in 24 hours by jaundice. The hæmoglobinuria persisted for five days and left her extremely weak, so that she was unable to rise from her bed for six weeks. Her previous history was negative, and no other member of the family had ever had anæmia or jaundice. Similar attacks occurred at Christmas, 1929, and in March, 1930. She was not strong enough to travel till June, 1930, when she was taken to a hospital and transfused on account of her grave anæmia. A hæmolytic crisis followed the transfusion and she was not improved. Another spontaneous attack occurred a week before her admission to Guy's Hospital. In addition she was then three months' pregnant.

She had a severe anæmia, red cells 1,480,000 per c.mm., hæmoglobin 27 per cent., colour-index 0·9, white cells 4000, platelets 120,000. The differential white count, and the clotting and bleeding times were normal. The mean diameter of the red cells was 7·8 microns. Van den Bergh's reaction was only faintly positive. The resistance of the red cells to hypotonic saline was normal at the first examination (0·45/0·35), but two and a half months later it was diminished (0·55/0·45). Wassermann's reaction was negative and the blood did not hæmolyse on exposure to cold. Physical examination was negative except for anæmia and a spleen two fingers below the costal margin. There were no alimentary symptoms and the test-meal was normal. The urine was chemically and microscopically normal and contained no iron pigment. X rays, cystoscopy, and renal function tests revealed no disease of the kidney. She aborted nine weeks after admission with slight clinical improvement.

The course of the anæmia during the three months she was in hospital is shown in Fig. 1. Massive doses of iron and liver had no effect. The reticulocyte count was always high, but in spite of a reticulocytosis more than ten times the normal, the red count did not rise. Blood formation was much accelerated and the persistence of the anæmia can only be explained by persistent excessive hæmolysis. Now, seven months later, there have been no more acute hæmolytic crises and the blood count is: red cells, 2,570,000 per c.mm.; hæmoglobin, 50 per cent.; colour-index, 0.9; white cells, 3600; reticulocytes, 8 per cent. Her Price-Jones curve, which showed a high normal red cell diameter, is contrasted in Fig. 2 with an acholuric jaundice curve published by Hampson and Warner.

The disease is rare, and only two cases have been admitted to Guy's Hospital during the last ten years. P. N. Panton and co-workers described three cases, in addition to two closely related non-syphilitic paroxysmal hæmoglobinurias, in a review of a series of grave anæmias which included 117 pernicious anæmias. Isolated cases have been described by many authors and small groups of cases by Adler, Bergmark, and Micheli (1930). The mixed series of cases of non-Addisonian hæmolytic anæmia reported by L. S. P. Davidson and by G. W. Goodhart also include examples. The disease appears at all ages, most often in young adults. The anæmia is often severe, the colour-index variable but usually about unity. The most striking feature is the great and persistent increase of reticulocytes. Nucleated red cells including megaloblasts are often seen. In perhaps half the cases there are periodic exacerbations of hæmolysis, productive of hæmoglobinuria and jaundice. At these times there may be leucocytosis and occasional myelocytes, but in the chronic phase white cells are rather diminished in numbers. The spleen may or may not be enlarged. Nutrition and digestion are normal. The disease may prove fatal after a course of several years. Post mortem "the characteristic changes of pernicious anæmia are found."[53] Micheli (1931) has separated under the title of hæmosiderinuria a group of cases in which the liver and spleen are not enlarged, iron pigment is present in the urine, and hæmosiderosis is concentrated in the kidney. Detailed classification of s type is premature when knowledge is so imperfect, l Panton showed that iron pigmentation might be efly localised in the skin.

These cases differ from congenital acholuric ndice in the absence of a family history and in the e and shape of their red cells. In acholuric ndice the red cells are small and spherical. while acquired hæmolytic anæmia they are usually a le larger than normal and not spherical (cf. Fig. 2). e fragility may be impaired in both diseases, ough more constantly in acholuric jaundice. pathology these anæmias are obviously quite ferent from pernicious anæmia, being the result increased blood destruction and not of diminished mation. They show some features in common th the hæmolytic crises of late syphilis and malaria, t differ in their persistent hæmolysis. A similar pe of anæmia sometimes occurs in aleukæmic kæmia, and more seldom in Hodgkin's disease. ese comparisons suggest the possibility of morbid anges in the body fluids or the reticulo-endothelial stem. When the spleen is enlarged, benefit may llow its removal but cannot be promised with e same confidence as in acholuric jaundice. Medical eatment is ineffective and transfusion often harmful.

Anæmia in Childhood.

Before discussing the acute hæmolytic anæmias, must make a short digression into the anæmias of fancy and childhood, and here, as my own experience small, I will follow closely Nobécourt's description. he anæmias of infancy and childhood are still nperfectly understood. This is due partly to the ifficulty of investigating these little patients, but ven more to the lability of the erythron at this time f life. Leaving on one side anæmias due to diseases of he liver and spleen, of the white cells, and of the latelets—and in practice it is not always easy to ifferentiate them from diseases of the erythron tself—the pediatrician is accustomed to divide the næmias of infancy and childhood into the mild or imple, and the severe or grave. The *simple*, which re usually of a chlorotic type, do not concern us now.

The grave anæmias of childhood sometimes date from an acute infection such as measles but just as often there is no apparent cause. They fall into two groups, the aplastic and the plastic; intermediate forms of a hypoplastic type also seem to occur. In the *aplastic anæmia* morphological changes in the red cells are absent, there is little anisocytosis or polychromasia, there are no nucleated red cells. and the white cells are diminished in numbers. The disease undoubtedly corresponds with the aplastic anæmia of later life. Death may occur from the complete failure of the marrow, or, more often than in adults, there is a gradual resumption of function. This aplastic anæmia will not be referred to again. In the *plastic anæmia* of childhood there is much anisocytosis and polychromasia, normoblasts and megaloblasts circulate in the peripheral blood the white cells are much increased in numbers. and large numbers of myelocytes may be present. The spleen may be enlarged and more rarely lymph glands are palpable. This type of anæmia is most common in sucklings, and of 124 cases collected by Hallez (quoted by Nobécourt) 120 were less than 2 years of age and the majority from 6 to 20 months. It is this type of anæmia occurring in infants which is often known as the pseudoleukæmia of von Jaksch. but von Jaksch's syndrome is at present in the melting pot. and I shall therefore make no further reference to anæmia in infancy.

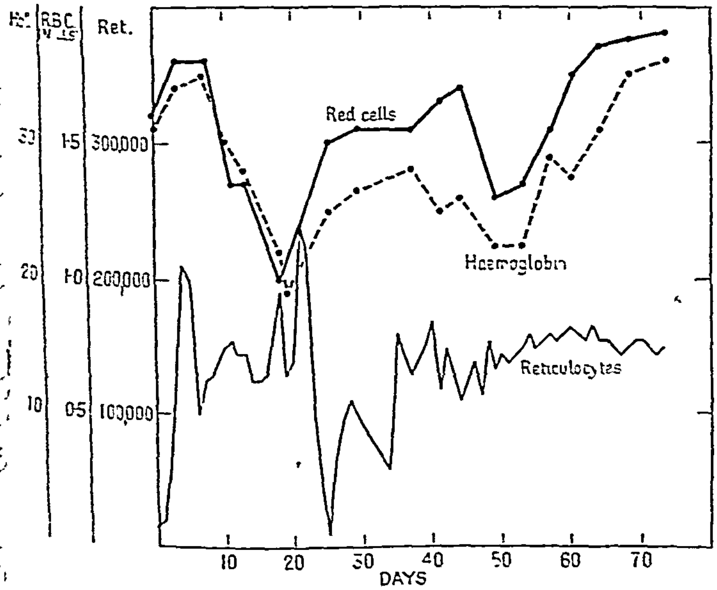
Price-Jones curves in chronic acquired hæmolytic anæmia and in acholuric jaundice.

FIG. 1.



Persistent reticulocytosis in chronic hæmolytic anæmia.

Acute Hæmolytic Anæmia.

In discussing these plastic anæmias Nobécourt refers to several cases of the same type he has encountered in later childhood and in adults. From a study of the literature and of a series of cases observed by R. J. L. O'Donoghue and myself at Guy's Hospital, I have felt that it will be profitable to collect them together and discuss them in some detail. Our subject opens in the year 1900, when Leube reported a case of rapidly fatal anæmia in a boy aged 10, whose peripheral blood showed anæmia of high colour-index with normoblasts and megaloblasts and only moderate increase in white cells, while the morbid changes after death were those of acute leukæmia. He suggested the possibility of a disease which combined the features of leukæmia and pernicious anæmia, and gave it the name leukanæmia. With accessions of knowledge and the reorientation of hæmatology in recent years, much of the controversy which followed Leube's paper has become meaningless, and the term leukanæmia should be banished from our writings. Cases diagnosed leukanæmia were leukæmia with secondary disturbance of the erythron, or pernicious anæmia with secondary myeloid effects, or perhaps most commonly they were acute hæmolytic anæmia of the type which we are now considering. The important result was the publication of a number of cases of grave anæmia which were characterised by simultaneous and profound disturbance of the erythroblastic and myeloid tissues, and which differed biologically from the incurable diseases pernicious anæmia and leukæmia in that they might recover completely and permanently.

The thesis I wish to present is that the cases variously described as acute hæmolytic anæmia (Lederer), acute febrile anæmia (Brill, Benhamou, Moschcowitz), acute leukæmia with recovery, acute pernicious anæmia with recovery, many of the so-called septic or non-Addisonian hæmolytic anæmias, and many of the plastic anæmias of childhood, should be regarded as examples of one and the same disease or morbid process. *I shall also suggest that the acute hæmolytic anæmia of pregnancy is the same disease occurring with special frequency in the pregnant woman, and I shall show that in clinical features and hæmatology it is identical, differing only in its resistance to treatment while the fœtus is in utero.* The disease may vary greatly in acuteness and in the *emphasis of individual symptoms*, but in clinical course, blood picture, pathology, and treatment, the cases form a coherent group, in which the differences shade imperceptibly from one case to another. Parkes Weber has aptly termed them acute anæmic breakdowns, and it will be helpful to future research if we discuss their natural history and pathology in an objective fashion. The disease is rare and we have had only six cases during the last ten years at Guy's Hospital, of which the following is a typical example:

A man, aged 42, was admitted to Guy's Hospital with jaundice and anæmia in June, 1922. His illness had begun suddenly with a slight rigor five weeks before. His previous health had been good except for malaria when he was soldiering in India. A paternal uncle was said to have died of jaundice, and of his ten children, five had died young, two of jaundice. He had not been in contact with any chemical or known poison. The temperature was raised to 100° for two days after admission and thereafter was normal. He had general yellow jaundice and the spleen was just palpable. The fæces were normally pigmented, the urine contained urobilin, no bile. The test-meal was normal. The indirect van den Bergh reaction was positive. Without any treatment he made a rapid improvement as shown in Table I. Nine years later he had remained perfectly well, and physical examination was negative. The blood count and the fragility of the red cells were normal and the van den Bergh reaction was negative.

The disease affects males and females equally. It occurs at all ages but is more common in the first and second decades. The onset is often abrupt with fever, influenzoid symptoms, sore-throat, or biliousness. *Hæmoglobinuria* has been described but is unusual,[38] and there is a variable degree of jaundice. The pace of the disease varies, and it may be only a few days or on the other hand several weeks before the anæmia attracts attention. By this time the red cells have fallen below two million and may be *only a few hundred thousand*. The colour-index is about unity. The diameter of the red cells is sometimes diminished, sometimes increased. There is a high reticulocytosis, often 30 per cent. or more, and large numbers of megaloblasts and normoblasts may appear. The fragility of the red cells may be normal, or it may be increased, *returning to normal* when the anæmia is repaired. Van den Bergh's reaction is positive. The white cells are often much increased in number and immature cells may enter the circulation and simulate leukæmia. The platelets are diminished and petechiæ, purpura, or spontaneous hæmorrhages may develop.

TABLE I.

Date.	Red cells.	White cells.	*Hb.* %.	Colour index.
12/6/22	696,000	—	22	1·6
16/6/22	1,688,000	6,420	36	1·1
19/6/22	2,384,000	—	44	0·9
22/6/22	3,400,000	—	50	0·7
27/6/22	2,856,000	—	58	1·0
30/6/22	3,150,000	—	56	0·9
22/7/31	4,800,000	6,000	89	0·9

Normal resistance to [illegible] saline was found by Christiansen, Fiessinger [illegible] Weber; low resistance by Holst, [illegible] 0·80/0·19, Benhamou, 0·52/0·40, rising to 0·46/0·38 on recovery.

Weber's patient, aged 11, had 25,000 white cells, of which 71 per cent. were lymphocytes, 17 per cent. normoblasts, and 5 per cent. megaloblasts. Lederer's patient, aged 24, had 44,000 white cells, of which 1 per cent. were myelocytes, *8 per cent. normoblasts, and 1 per cent.* megaloblasts. Holsti's patient, aged 37, had 45,000 white cells, of which 79·7 per cent. were myelocytes. Teeter's patient, aged 6, had 133,000 white cells with 11 per cent. myelocytes, 6 per cent. myeloblasts, and many normoblasts and megaloblasts. All these patients made a permanent recovery.

The clinical picture is that of a severe systemic infection. The temperature ranges from 99° to 105°. The face is swollen and the *limbs often* œdematous. Red patches like Osler's nodes sometimes develop on the hands, and subcutaneous blebs on the limbs and elsewhere. The colour is pale, café-au-lait, lemon-yellow or jaundiced, but as a rule the patient is more anæmic than icteric. The test-meal is normal. The liver, spleen, and less often the glands in the neck, axilla, and groins, may be enlarged. If there is a hæmorrhagic tendency, retinal hæmorrhages, epistaxis, gingivitis, hæmatemesis, or melæna occur. The urine may contain a trace of albumin, a few red or white corpuscles, and much urobilin. The condition of the heart may cause difficulty in diagnosis:—

> "As the anæmia progresses the first sound at the impulse becomes short and abrupt, and if in addition it is slightly reduplicated the simulation of mitral stenosis is very close. We have not detected in such cases a definite thrill, but there is invariably a soft systolic murmur after the abrupt first sound. When the degree of anæmia is very profound, a diastolic murmur may also become evident at the base, with its maximum usually just to the left of the sternum in the second intercostal space. When in addition there are fever, purpura, and enlargement of the spleen, the resemblance to a progressive endocarditis is so close as to give rise to the greatest difficulty in diagnosis. It is equally remarkable when there is improvement in the anæmia, how completely these cardiac signs alter and return to the normal."[59]

In addition there may be a pericardial rub. With all these symptoms, so suggestive of a septicæmia, the blood culture and the serum reactions to all known organisms are negative. The mortality of the untreated disease is probably about 50 per cent. The fever lasts from a few days to several months l there is no hard-and-fast line between the acute l subacute cases. As long as the temperature is ied, hæmolysis seems to be active, for anæmia l reticulocytosis persist, but if the patient survives crisis, recovery is spontaneous, complete, and manent. In cases coming to autopsy there are lespread fatty degeneration and iron pigmentation the viscera. Hæmorrhages may be present in the in and elsewhere. The spleen is large, and in the ite cases dark and red and soft. its sinuses engorged th blood. The bone-marrow is hyperplastic, roon coloured or like red-currant jelly, and it itains many megaloblasts and usually myelocytes o. In Moschcowitz's case there were hyaline thrombi many organs, composed of agglutinated red cells, d in other cases sterile infarcts of the spleen and eptic necroses of the lymph glands have been found. icteriological examination is negative except for few cases explained by contamination.

In the treatment of acute hæmolytic anæmia iron, senic, and removal of septic foci do no good. Liver is been introduced too recently for its value to be sessed and it has been used only in cases which might ell have recovered by their own forces. The most riking feature of the treatment of acute hæmolytic iæmia is the dramatic effect of transfusion, often served in patients who seemed moribund. The mperature falls and a rapid recovery sets in. More ian one transfusion may be necessary to arrest the æmolytic process, but in cases properly treated by ransfusion, death is a rare event. This specific ction of transfusion is observed in no other blood isease except the hæmolytic anæmia of pregnancy, hough there is a parallel in the cure of icterus gravis ieonatorum by serum. With this observation I shall eave theoretical consideration of acute hæmolytic anæmia till I have discussed the hæmolytic anæmia of pregnancy.

(*To be concluded.*)

DISSEMINATED SCLEROSIS.

CLINICAL AND SEROLOGICAL OBSERVATIONS DURING EXPERIMENTAL VACCINE TREATMENT.

BY SIR JAMES PURVES-STEWART, K.C.M.G., C.B., M.D. EDIN., F.R.C.P. LOND.,
CONSULTING PHYSICIAN TO WESTMINSTER HOSPITAL;
AND
F. D. M. HOCKING, M.B., M.SC. LOND.,
BIOCHEMIST AND ASSISTANT PATHOLOGIST TO WESTMINSTER HOSPITAL.

IN March, 1930, one of us [1] published a preliminary article describing some results of treatment in disseminated sclerosis by means of an autogenous vaccine prepared from the cerebro-spinal fluid.

The bacteriological basis on which this treatment was originally founded was the presence of a characteristic ultra-microscopic spherula, described in the same number of THE LANCET by Miss K. Chevassut [2] as occurring in the cerebro-spinal fluid of patients suffering from disseminated sclerosis when this fluid was incubated with Hartley's broth and human blood-serum. According to Miss Chevassut, this characteristic spherula was observed by her in 176 out of 189 cases (i.e., a percentage of 93 per cent.), whilst in a control series of 269 cases, comprising normal persons as well as patients suffering from other organic nervous maladies, she recorded uniformly negative results. The occurrence of a positive colloidal gold curve, similar to that already noted by previous observers, was confirmed. In addition, she described a characteristic acid wave as occurring in cultures of the spherula, claiming that the pH of such cultures underwent a temporary reduction from 7·6 to 7·0, lasting for about five days before returning to the previous level; subsequent to which the alkalinity increased up to about 8.

This bacteriological work has most properly been subjected to critical examination by independent workers. The results are conflicting. Confirmatory observations as to the presence of the spherula in disseminated sclerosis and its absence in control cases were published by Smith and Ransome,[3] of Liverpool, who found the spherula present in 11 out of 12 cases of disseminated sclerosis and absent in control cases; also by von Sarbó,[4] of Budapest, who found the spherula present in over 100 cases. On the other hand, Carmichael,[5] of London, consistently failed to find the spherula in a series of 19 cultures from cases of disseminated sclerosis, although he, like Miss Chevassut, had the advantage of consultation with Mr. J. E. Barnard as regards the necessary ultra-microscopic technique. Carmichael also failed to observe any acid wave in broth cultures of the spherula. His estimations, however, of the pH were made by using a rocking electrode instead of the bubbling electrode used by Chevassut, and cannot therefore be regarded as strictly comparable. Carmichael's observations on the colloidal gold curve were in agreement, broadly speaking, with those of Miss Chevassut and of other observers.

Further critical observations on the bacteriological side of the research have since been forthcoming from various other sources. These are at variance in several respects, not only with Chevassut's but also with Carmichael's work. Thus, for example, Lépine and Mollaret [6] in Paris demonstrated the presence of an ultra-microscopic spherula, not only in 12 cases of disseminated sclerosis but also in six control cases from other organic nervous diseases, and even in Hartley's broth without admixture of cerebro-spinal fluid, and also in the aqueous humour of the rabbit after injection of a drop of human serum. They failed to confirm the occurrence of an acid wave in cultures from the cerebro-spinal fluid in disseminated sclerosis. They came to the conclusion that the ultra-microscopic spherula was probably not a living virus, and nor was it a specific appearance in disseminated sclerosis. Tronconi [7] in Pavia and Hicks and Hocking [8] at Westminster have also demonstrated the presence of a spherula in various degenerative diseases of the central nervous system other than disseminated sclerosis. The observations of one of us (F. D. M. H.) are, in the main, in agreement with these latter observers.

For reasons already set forth,[9] [10] we have dissociated ourselves from Miss Chevassut. The research, however, has been continued in our special laboratories at Westminster Hospital Medical School. This present paper of ours is based upon observations on a further series of 101 consecutive cases of disseminated sclerosis examined clinically and serologically within a period of six months from March to September, 1931.

CLASSIFICATION OF CASES.

Our 101 cases, of which 22 were early, 62 moderate, and 17 advanced, have been classified, not according to the duration of their signs and symptoms, but according to the stage of the malady which had been reached when the patient first came under observation.

By this standard, an *early* case is one in which the physical signs, whilst sufficiently definite to establish a positive diagnosis (e.g., an extensor plantar response, pallor of one or both optic discs, nystagmus, absence of one or more abdominal reflexes, &c.), are so slight as not to interfere in any way with the patient's ordinary daily activities. Twenty-two of our cases belonged to this category. Amongst them were included several patients whose first symptoms dated back 14, 13, and 11 years respectively; others had only shown symptoms for five or six months, whilst the average duration of these early cases was four years.

A *moderate* case, according to our classification, is one with well-marked physical signs and symptoms, evident not only to the physician but also to the patient and his friends (e.g., weakness, spasticity or ataxia of the upper or lower limbs, visual impairment, diplopia, increased tendon-jerks, clonus, &c.), but in which the patient is still capable of carrying on his daily occupation and of earning his living. Sixty-two of our present series of 101 cases belonged to this moderate class, and had an average duration of 7·8 years.

An *advanced* case is one in which the patient's physical disabilities are so severe as to remove him from the class of active citizens, so that he is no longer able to carry on his ordinary occupation but has become an invalid, dependent on his family or friends, getting about with support or even confined to a chair. In our present series 17 cases, by the time they came under observation, were in this advanced stage. The duration of their symptoms varied from less than a year in two acute fulminating cases, up to 28 years in the case of longest standing. The average duration of these advanced cases before coming under observation was 9·3 years.

All the foregoing 101 cases were treated by repeated courses of an autogenous "vaccine" prepared from the spherula cultured in the cerebro-spinal fluid. In most cases this was made according to the method detailed by Hicks and Hocking[11] in doses graduated from 1 million to 200 millions or more. In some cases, however, a simpler volumetric method, as described by von Sarbó,[4] was used, with a weekly dosage ascending from 1 to 10 c.cm. The ordinary duration of a vaccine course was 12 weeks. Before starting a fresh course careful observations, clinical and serological, were carried out in every case.

It should be emphasised that whenever the term "actively growing" or "positive" culture is made in the present paper, it is meant that such cultures show a progressive increase in the number of observable spherules and granules by dark-ground illumination, and not that these particles necessarily constitute either a virus or a living organism.

In view of our uncertainty as to whether the spherula is a virus or merely a biochemical precipitate, we frankly admit that the accuracy of the word "vaccine" is open to criticism. For convenience, however, we have preferred to retain the term for the present.

SEROLOGICAL OBSERVATIONS.

Before detailing the results of our serological investigations, we think it desirable to define the appearances which in our opinion constitute a "positive" culture, as contrasted with one or other of the filtrable contaminants for which it might be mistaken.

Cultural Observations.—One of us (F. D. M. H.), in conjunction with Braxton Hicks,[8] has already drawn attention to the fact that for the satisfactory demonstration of the spherula, the necessary cultural conditions are less strict than those originally described by Chevassut.

Mixtures of normal human serum 3 parts with Hartley's broth 5 parts, after passage through a Berkfeld or Seitz filter, yield a fluid which is optically clear, both to the naked eye and when viewed microscopically by dark-ground illumination. Occasionally a few faintly illuminated granules may be seen showing active Brownian movement, or an unresolved haze; these appearances we regard as filtrable contaminants. On incubating the mixture up to a period of 14 days, no alteration in optical properties occurs, except perhaps that the filter-passing contaminants, if present, may increase in numbers. Such non-specific bodies, all of them feebly illuminated, appear as granules, spheres, or ovoid bodies, the latter being about twice the diameter of the spherule commonly seen in disseminated sclerosis.

When the broth-serum mixture is incubated with cerebro-spinal fluid from a case of disseminated sclerosis a change occurs, sometimes within 24 hours, sometimes only after longer periods—e.g., not until after seven days' incubation. This change consists of a naked-eye opalescence which develops in the incubated tube as opposed to a persistence of clarity in the control tubes. The opalescence becomes more pronounced as incubation continues, but no actual precipitate forms. On microscopical examination with dark-ground illumination, this opalescence is seen to be due to the presence of brighly illuminated spherules of varying sizes up to about 0·25 μ in diameter. The larger spheres reflect light only from their periphery, thus appearing as bright rings each surrounding a central dark space. In the smaller spheres the central dark space is reduced to a mere dot, whilst still smaller particles appear as bright granules only. In addition, a number of more faintly illuminated particles, still smaller, are observed. At this stage of incubation there is no tendency for the particles to aggregate together, and they are actively motile with a characteristic vibratile Brownian movement. When left illuminated on the microscopic stage for long periods—e.g., an hour or more—most of these particles appear to settle down and lose their movement, even when drying of the preparation is prevented by sealing down the cover-slip. A similar but transient slowing or cessation of movement has been described by Guardincerri (in a private communication to us) when cultures are exposed to the action of ether or chloroform vapour. In such circumstances he has noted the return of motility when the effects of the vapour have worn off. So far, we have not been able to reproduce this phenomenon.

As incubation proceeds, both spheres and granules increase in numbers, the former at a greater rate than th latter. It is conceivable, therefore, that the process i one of gradual development from granule into spherule A tendency to aggregation of particles may now be observed in which relatively large spherules are seen to which ar attached both granules and smaller spherules. This proces of aggregation is never a very marked feature of thes cultures, it being rare to see a total of more than four o five elements thus aggregated. Large colonies, such a those originally described by Chevassut, have not bee observed by us, whether in serum-broth cultures or by th agar-slip method devised by Welch.[12]

Finding ourselves unable to corroborate the presence o these large colonies, both von Sarbó and ourselves hav accordingly discarded the slip method of examination, an now rely upon the appearances developing in liquid cultures

Whilst aggregation occurs as above described, no coalescence of particles to form large single bodies or droplet has been noted by us. Each particle appears to attain it maximum size (approximately 0·25 μ to 0·3 μ), and the remains discrete. It is possible that this aggregation o agglutination phenomenon is due to adsorption of protei on the surface of the developing spherules, thus formin around them a skin of precipitated albuminous materia differing in composition from the main bulk of the particle Such a physical barrier would effectively prevent th running together of liquid particles to form large droplets

If incubation be continued for a further period—viz., u to 14 days—the only further change observed is an increas in the number of spheres and granules.

With regard to the filamentous structures described b Chevassut, these are inconstant and late in appearance When they occur the filaments vary in length from approximately 0·1 μ to 2 μ, and are excessively fine and tenuous They are best seen either in "strongly positive" cultures or in those which are relatively old—i.e., 7 to 14 days The filaments occur in conjunction both with spherule and granules. They are never observed as simple unattache entities. When present, they serve to link together a vary ing number from two to six spheres or granules. Th commonest arrangement is that of a central sphere to whic are attached one or more filaments of varying length wit nules or small spheres at their free ends. Occasionally nents are seen crossing each other transversely, with ll refractile granules at the free extremities of each ment.

till another appearance is not infrequently observed, more often in disseminated sclerosis than in other es of organic disease—viz., a straight, beaded rod-like n about 4μ long and 0·15μ in diameter. This rod ticipates in the general Brownian movement but has no tility of its own.

loid bodies, or appearances suggestive of "budding," ve never been observed by us in uncontaminated cultures. n all cases illuminated by transmitted light the micro-pical field is completely blank. Dark-ground illumina-n is essential to yield the foregoing appearances. No racteristic staining reactions have yet been discovered. tempts to dissolve out the spheres and granules by fat vents have failed, but this failure may possibly be asso-ted with the presence of the adsorbed protein skin und the particles as above suggested.

In our experience the foregoing ultra-microscopical pearances are not produced by incubation of normal rebro-spinal fluids. They occur with great fre-ency in disseminated sclerosis, but they are not thognomonic of the disease, since they are also en in cultures from other organic nervous diseases, seen in the following list :—

Tabes	.. 7 cases.	
Tabo-paralysis	.. 6 ,,	out of 7.
Cerebral tumour	.. 3 ,,	
Cerebral thrombosis	.. 2 ,,	
Cerebral abscess	.. 1 case.	
Subacute combined degeneration	.. 3 cases.	
Amyotrophic lateral sclerosis	.. 1 case.	
Uræmia	.. 1 ,,	out of 3.
Tuberculous meningitis ..	.. 2 cases.	
Parkinson's disease	.. 1 case	out of 2.
Amentia	.. 1 ,,	
Total	..28	

On the other hand, negative cultures were obtained n the following :—

Normal individuals	.. 4 cases.	
Hysteria	.. 5 ,,	
Vertebral scoliosis	.. 1 case.	
Tabo-paralysis	.. 1 ,,	out of 7.
Uræmia	.. 2 cases	out of 3.
Parkinson's disease	.. 1 case	out of 2.
Total ..	..14	

We would also draw attention to the fact that identical spheres and granules can be seen in many other pathological serous fluids—e.g., serous pleural fluid, serous peritoneal fluid, or serum from chancres—and also in serum-broth cultures that have become contaminated with pathological micro-organisms. If, however, the spheres and granules are removed from such serous fluids by filtration, in only very few instances will they reappear on subsequent incubation. Cases in which reappearance does occur are generally those which had originally contained pus, together with their filtrable enzymes which might subsequently effect a breakdown of serum constituents. "Positive" cultures from cases of disseminated sclerosis can be rendered optically clear, naked-eye and microscopically, by filtration, but re-incubation will constantly reproduce the initial characteristic appearances. This process of filtration and re-incubation can be repeated several times in succession, although the development of granules, &c., tends to slow up after continuous repetition. Optically clear fluid obtained by filtration from a "positive" culture will also reproduce a characteristic appearance when subcultured into fresh broth-serum mixture.

SEROLOGICAL OBSERVATIONS AFTER AUTOGENOUS VACCINE TREATMENT.

A. *Cultural Results.*—Bearing in mind the above criteria of a "positive" culture, we have observed that 10 out of our present series of 101 cases of disseminated sclerosis have become negative during courses of vaccine treatment, whilst 26 cases after showing initially a strongly positive result have become faintly positive. By "faintly positive" we mean either a smaller number of spheres and granules or their delayed appearance—i.e., not until five or seven days after starting the culture. With one exception, all the cases which have become culturally negative after treatment have also shown marked clinical improvement. In four cases, cultures after being positive on several successive occasions have gradually become negative, then for a short while positive again, and finally negative. Here again these findings are associated with clinical improvement.

B. *Globulin and Albumin Content.*—The globulin reaction in the cerebro-spinal fluid has been determined by the usual Nonne-Apelt ring precipitation test. In 72 out of our 101 cases a positive result was obtained at the outset, and in 24 of these the reaction after treatment became negative or only very faintly positive. This diminution in globulin reaction was not always strictly parallel to the clinical improvement, since many of our cases which showed the greatest degree of clinical improvement still yielded a definite globulin reaction. The total albumin content was also systematically observed and in all cases was within normal limits, up to 0·02 per cent.

C. *Colloidal Gold Curve.*—There has been a considerable controversy on the subject of the colloidal gold curve in the cerebro-spinal fluid in disseminated sclerosis, chiefly owing to the difficulty experienced in securing a standardised gold-sol preparation. In our series of cases the colloidal gold solution was made up by formaldehyde reduction in an alkaline medium (potassium bicarbonate). It was finally tested for sensitivity by saline solution, and also by the method of Black, Rosenberg, and McBride.[13] Solutions made up independently in two different laboratories, and tested on the same sample of cerebro-spinal fluid, have always yielded identical results. In agreement with Chevassut these show that the degree of precipitation in disseminated sclerosis is greater than that usually described as typical of this condition, complete precipitation in a number of tubes being by no means uncommon. A fairly typical curve when the patient first comes under observation is 334541000. After a course of vaccine treatment it is not uncommon for the gold curve to improve in type. Only rarely (in 8 out of 101 cases) has it become negative. Definite improvement was seen in 35 cases, 11 became more intense, and the remaining 47 were practically unchanged.

D. *Blood Counts.*—In view of a paper published by Goodall and Slater[14] suggesting a relationship between disseminated sclerosis and subacute combined degeneration of the spinal cord, all our patients in this present series had routine blood examinations carried out, including estimation of hæmoglobin, enumeration of red blood corpuscles, also a total and differential leucocyte count. In none of our cases was there any degree of anæmia present, or any deviation from the normal total and relative proportions of white cells.

E. *Liver Function Tests.*—In her original article, Chevassut described certain tests the results of which suggested impairment of liver function in patients suffering from disseminated sclerosis. These tests have been repeated by us. In only one of our 101 cases was the glycuronic acid test negative after the ingestion of 10 gr. of aspirin, and in only five cases was there an excess of indican in the urine. In a

The serum from C. E. H. was obtained six months after infection. A. E. G., although he had received 10 c.cm. of immune serum from C. E. H., four months previously was found when first tested to be devoid of complement-fixing antibodies. A few days after this test had been performed, A. E. G. contracted Rift Valley fever as a result of assisting at the autopsy of a lamb which was suffering from Rift Valley fever. Fourteen days later complement-fixing antibodies were present in the sera. Protective antibodies, capable of neutralising 1000 m.l.d. (minimum lethal doses) of virus, as shown by the action of the serum in protecting mice against infection with the virus, were detected in the serum nine days after infection.

G. M. F. also had an injection of 10 c.cm. of immune serum from C. E. H. When four months later his serum was tested for complement-fixing antibodies it was found to give a positive reaction, although not quite to the same extent as the sera from definite cases. Protective antibodies capable of neutralising 100 m.l.d. of virus were also present. G. M. F. had *not suffered from any symptoms attributable to* Rift Valley fever although he had performed a number of autopsies on infected animals. It is thus possible to acquire complement-fixing antibodies in the absence of any definite infection.

Table I. shows that fixation is specific for Rift Valley fever and does not occur with normal serum, with sera from syphilitics, nor with serum from recovered cases of dengue and yellow fever. Complement-fixing antibodies remain in the blood for at least six months after infection.

Complement Fixation with the Sera of Susceptible Animals.

In Table II. are shown the effects of complement *fixation with the sera of monkeys (M. rhesus)* recovered from the infection three to five months previously.

TABLE II.—*Complement Fixation with Monkey (M. rhesus) Sera.*

,, 10	+	+	–	–					

No C.S.I. = No clinical symptoms of infection.

No fixation occurred with the sera of normal monkeys; incidentally two of the monkeys included as normal had recovered from yellow fever 18 months previously. It will be noted that monkey 12, which failed to give any clinical evidence of infection, fixed complement less actively than the others.

Complement-fixation tests with sheep have been limited to two animals, an adult ewe, inoculated with a Berkefeld filtrate from the livers of two mice; and a lamb, inoculated with infected sheep blood which had been preserved for five months at 4° C. The lamb showed only a very temporary rise of temperature and no great constitutional disturbance, but the ewe had more definite symptoms with a rectal temperature of 107·8° F. (Findlay, 1932). The results are shown in Table III.

Three months after infection the sheep still fixed complement but negative results were obtained with the lamb's serum. Protective antibodies had also *disappeared from this animal's* serum, though the sheep's serum was still able to neutralise 1000 m.l.d. of virus.

In Table IV. are shown the results obtained with the sera of rats and mice. In the case of these animals the complement-fixing antibodies disappear from the sera with considerable rapidity, so that while the most recently recovered animals fix complement, after the lapse of two months from the date of infection complement-fixing antibodies are so reduced as to be no longer detectable by the present test. Mice appear to produce only very small quantities of complement-fixing antibodies. This may be correlated with the fact that recovery from infection does not confer any lasting immunity in rats and mice which can be reinfected four to six weeks after their first infection. On the other hand, it has been found impossible to reinfect monkeys even six months *after a primary infection.*

TABLE IV.—*Complement Fixation with Sera of Rats and Mice.*

					6	–	–	–	–

No positive complement fixation was obtained with the sera of rabbits, guinea-pigs, hens, pigeons, and canaries, animals which have been found to be resistant to infection with the virus of Rift Valley fever.

The Use of Dried Virus.—In the foregoing experiments the antigen used was prepared from the livers of freshly killed mice or rats. *It is possible,* however, to employ an antigen prepared from mouse livers which have been dried over phosphorus pentoxide.

Mouse 898 was killed on Nov. 20th, 1931, with symptoms of Rift Valley fever; its liver was finely minced and placed in a desiccator over phosphorus pentoxide at a temperature of +4° C. Fifty-six days later the dried tissues were found still to contain virus for 0·5 c.cm. of a 1 in 10 dilution in physiological saline inoculated into each of 4 mice killed 3 mice in 5 days and 1 in 7 days, a slight retardation in the usual time required to kill mice. A 1 in 250 saline extract of this dried mouse liver was then prepared and tested in a parallel series with a similarly prepared extract from the fresh liver of a mouse which had died from Rift Valley fever, allowance being made for the water content he fresh liver. The results are shown in Table V.; both gens were tested against human and monkey sera.

BLE V.—*Complement Fixation with Dried Antigen.*

Serum.	Concentration of antigen.			Controls.

The results were therefore rather less satisfactory an with the fresh liver, in conformity with the ndings that the dried liver was rather less rich in rus than fresh liver.

Discussion.

Specific complement fixation may thus be obtained ith the sera of man and animals who have suffered om Rift Valley fever, using as an antigen the vers of mice and rats suffering from the disease. omplement-fixing antibodies are present in the lood of men and monkeys for at least five to six onths after infection, while positive results are lso obtained with sheep three months after infection; no fixation was obtained with yellow fever mmune serum or dengue immune serum. Complement fixation thus offers a practical method for he diagnosis of Rift Valley fever. Complement-fixing antibodies were definitely detectable in the serum of A. E. G. 14 days after infection, and in the sheep and lamb about the same period. Protective antibodies were present in the case of A. E. G. nine days after the beginning of the illness at which time complement-fixing antibodies could not be detected. Protective antibodies were also present in the sera of the sheep and lamb seven to nine days after infection. Although further evidence is required on this point, it seems likely that protective antibodies are demonstrable in the serum at a somewhat earlier date than complement-fixing antibodies. Hudson (1931) has recently made similar observations in five cases of yellow fever in man. It may be noted that in the case of men, monkeys, and sheep the degree of complement fixation is in some measure correlated with the intensity of the clinical response to the infection.

Up to the present attempts to obtain flocculation or agglutination of the virus of Rift Valley fever with immune sera have failed, nor has it been possible to obtain evidence of skin sensitivity to the virus in those immune to the disease by the intradermal injection of killed virus.

CONCLUSIONS.

(1) Specific complement fixation occurs with the sera of men, monkeys, sheep, rats, and mice recovered from Rift Valley fever when an antigen of the livers of rats and mice infected with Rift Valley fever is employed. (2) Complement-fixing antibodies are well developed in the serum 14 days after infection, and persist for at least six months. (3) Complement-fixing antibodies may appear in the serum in the absence of any definite illness as a result of repeated exposures to infection. (4) The degree of complement fixation is in the case of men, sheep, and monkeys roughly proportional to the severity of the clinical symptoms. (5) Mice and rats produce only small quantities of both complement-fixing antibodies and protective antibodies. (6) Dried liver as an antigen gives less satisfactory results than fresh livers of infected animals.

RIFT VALLEY FEVER.

BY R. DAUBNEY, M.Sc., M.R.C.V.S.,
AND
J. R. HUDSON, B.Sc., M.R.C.V.S.
(From the Division of Veterinary Research, Kenya Colony.)

THE object of this note is to supplement the data given by Findlay and Daubney[1] on the susceptibility of various species of animals, more particularly wild rodents, to inoculation with the virus of Rift Valley fever, and to refer briefly to certain suggestions that were made in the course of the discussion[2] on Dr. Findlay's paper read before the Royal Society of Tropical Medicine and Hygiene.

As stated in our first paper[3] on the disease, the virus was considered to be closely related to the viruses of yellow fever and dengue, and the primary object in taking the virus to England was to ascertain whether any cross-immunity existed between these three viruses. The recent investigations of Schueffner, Dinger, and Snijders[4] on the immunological relationship of yellow fever and dengue were prompted by similar considerations. The Dutch workers wondered if the endemicity of dengue might not be the principal cause of the relative freedom of the Dutch East Indies from yellow fever, and we had indulged in a similar speculation with regard to Rift Valley fever and the absence of yellow fever from East Africa. The results of the actual experiments carried out by Dinger and Snijders[5] are hardly conclusive, and will require extension and confirmation, but the general tenor of their findings is that previous infection with yellow fever failed to protect monkeys (*Macacus rhesus*) against a subsequent infection with dengue, whereas a previous dengue infection conferred some degree of protection against a subsequent inoculation with yellow fever virus.

In the experiments arranged at the Wellcome Bureau of Scientific Research one monkey (*M. rhesus*), immune to yellow fever as a result of a previous infection, did not manifest any immunity against the virus of Rift Valley fever, other *rhesus* monkeys previously vaccinated by Mr. E. Hindle, D.Sc., against yellow fever also failed to show any increased resistance to the virus of Rift Valley fever. The converse experiment could not be tried, owing to the restrictions that have been placed upon the use of yellow fever virus in England.

In the same connexion it would be of considerable interest to compare the susceptibility of various species of African and Asiatic monkeys to Rift Valley fever. The only two African monkeys that have so far been inoculated with the virus in Kenya have failed to react, as judged by subinoculations of their blood into susceptible sheep.

POSSIBLE VECTORS.

Rodents.—The demonstration of the high susceptibility of some European rodents at once recalled to

M 2

mind the fact that during the original outbreak in the Rift Valley there had been a considerable mortality, which was referred to plague, among wild rats (*Arvicanthis abyssinicus nairobæ* and *Rattus rattus kijabius*) on the affected farms; and, in fact, on the farm where the most serious losses of sheep from Rift Valley fever were recorded rodents died in such numbers that inoculation with plague vaccine was carried out. Later a search of the records of rat examinations at the Medical Research Laboratory, Nairobi, revealed that no cases of plague had been found in rats forwarded from this area of the Rift Valley during the period of the outbreak.

In order that the susceptibility of field rats might be examined, trapping was undertaken in an area from which Rift Valley fever has not been recorded, experienced natives being very kindly lent for the purpose by Messrs. Symes and Roberts, entomologists, at the Medical Research Laboratory.

In all, 80 *Arvicanthis abyssinicus nairobæ* were inoculated with strains of virus from sheep, from white mice, and in some cases from other arvicanthis. Of 57 arvicanthis inoculated with strains of virus from sheep or mice, 19 died within 20 days of the inoculation, average period 11 days, and 12 at least could be considered positive on the basis of naked-eye lesions and histological findings in the liver. The nature of the infection was further confirmed in a number of cases by subinoculations into mice and sheep, positive results being obtained at intervals from the second to twelfth day after inoculation. After one or more passages through arvicanthis the virus appeared to become considerably exalted for this species.

Mastomys coucha panya, which is a much rarer species in the Rift Valley fever area, appears to be less susceptible. Of 35 individuals inoculated with virus, only six succumbed to the infection.

Only three specimens of *Otomys angoniensis elassodon* have been available for inoculation: all died within five days of inoculation, with rather indefinite lesions. Since it is difficult to keep this species in captivity, it is not possible to draw any conclusion from this result.

Six wild *Rattus rattus kijabius* and one *Leggada bella* all survived inoculation with virus.

At the end of October, 1931, when trapping was commenced in the Rift Valley fever area, it was found that numbers of arvicanthis were dying on the farm where the original outbreak had occurred 15 months previously. Some of the rats that were trapped died in the traps before morning, a most unusual occurrence with this species which is quite tolerant of captivity. The livers were faintly mottled and organ smears usually showed no bacteria. Emulsions in oxalate-carbol-glycerin of the livers of 15 of these dead arvicanthis, and of one *Rhabdomys pumilio* which also died in a trap, were inoculated into lambs, mice, and into other arvicanthis obtained from an area free from Rift Valley fever. The results were uniformly negative, and histological examination of the livers did not reveal any specific lesion.

Ruminants.—With regard to the susceptibility of wild African ruminants we have up to the present only been able to inoculate one African buffalo.

This animal, a male of about seven months, which had been in captivity at the laboratory for six months, was inoculated with virus from a kid. He gave a marked temperature reaction with dullness and anorexia, and showed some stiffness of the limbs, recovering by the eleventh day.

Helminths.—Reference might be made to the species of tæniorhynchus that have been collected in the Rift Valley fever area.

Through a clerical error the name of species which was suspected as being a vector of the virus was previously given as *T. brevipalpis* instead of *T. fuscopennatus*. During the last season three species of this group (*Mansonia*) have been collected in the area and efforts are being made to establish transmission with all of them.

Arthropods.—In connexion with our suggestion that the virus is adapted for transmission by an arthropod vector, it may be of interest to relate that it has been proved to survive for a period of seven days in engorged nymphæ of *Rhipicephalus appendiculatus* that had been infected by feeding on a reacting sheep. Twenty-four days later, when the nymphæ had moulted to the adult stage, they failed to transmit the virus on inoculation into a susceptible sheep, nor did the other adults of the same batch transmit when allowed to feed on a susceptible animal.

CLINICAL CHARACTERISTICS.

In a personal communication Mr. R. E. Montgomery has asked us to search the laboratory records and, if possible, to trace the course of the investigations into a disease of young lambs to which he referred in the discussion of Dr. Findlay's recent paper on Rift Valley fever. Although no records of these investigations can be found, the lesions he describes—namely, the presence of discrete hæmorrhagic points in the parenchyma of the organ, leading to the development of necrotic centres as large as a threepenny piece, together with suppurative processes in the umbilical region—are not consistent with a diagnosis of Rift Valley fever.

The protocols of a second series of experiments with a mild febrile disease of cattle to which he also makes reference, had already been consulted before we wrote our original paper. The records, which consist of temperature charts and post-mortem sheets, indicate that he was dealing with an inoculable disease of domesticated ruminants with an incubation period of from 7 to 14 days, of which the agent did not pass Berkefeld or Chamberland filters in carefully controlled experiments. This disease does not appear to be either Rift Valley fever, three-day sickness, or heartwater.

As stated in our original paper [3] we have been able to obtain a history of earlier outbreaks of Rift Valley fever in lambs and adult sheep, in cattle, and in man. It is possible, and even probable, that Mr. Montgomery, in common with other veterinarians and medical men, saw cases of the disease, but was not favoured with the combination of circumstances which in 1930 enabled us to connect the disease in sheep with the much milder manifestations in bovines and in man.

Attention has also recently been drawn to clinical and pathological similarities between Rift Valley fever and three-day sickness of cattle.

We have already stated elsewhere [3] that there are available valuable records of inoculations of cattle and sheep with the virus of three-day sickness performed by Montgomery, in which it is shown that the incubation period of three-day sickness in cattle is from five to eight days and that the febrile reaction is invariably accompanied by some degree of lameness which may be so severe that the animals are unable to rise for some days. This is in complete agreement with the clinical picture of the disease as it occurs naturally. Moreover, Montgomery was unable to provoke reactions in any of 23 sheep inoculated with blood containing the virus. Bevan [6] obtained mild temperature reactions commencing from six to ten days after inoculation, in three sheep inoculated with the blood of cattle suffering from three-day sickness. No stiffness or lameness was observed and unfortunately no subinoculations were made into cattle to confirm the nature of the reaction. In his account of post-mortem findings in cattle dead of the disease he states that the liver, kidneys, and spleen showed no lesions, whereas our observations show that in fatal cases of Rift Valley fever in cattle, whether naturally contracted or experimentally induced, there is an unmistakably typical lesion of the liver. Further, although some stiffness of the limbs was shown by the infected buffalo mentioned earlier in the text, no lameness or stiffness of the limbs has been detected in any of the affected bovines that have been under observation.

While three-day sickness of cattle in all probability is a member of the same group of virus diseases, there is hardly room for doubt that it is quite distinct from Rift Valley fever.

CLINICAL AND LABORATORY NOTES

A CASE OF COMBINED DEGENERATION OF THE CORD TREATED WITH MASSIVE DOSAGE OF IRON.

L. V. SNOWMAN, M.B. CAMB., M.R.C.P. LOND.,
PHYSICIAN TO THE EASTERN DISPENSARY, WHITECHAPEL.

A WOMAN, aged 45, had been suffering from mptoms of pernicious anæmia since April, 1929. le had the typical lemon-yellow pigmentation, eakness, and dyspnœa, with an erythrocyte count 2,800,000 per c.mm., and hæmoglobin 70 per cent. le recovered after the administration of liver tract, but suffered two relapses owing to her having ased to take the liver. In September, 1931, her ythrocyte count had again fallen to 2,000,000, d her average pulse-rate while resting was 120. d she had slight œdema of the legs. At no time is there any glossitis.

After six weeks' liver treatment her erythrocyte unt reached 3,475,000, with 72 per cent. hæmoglobin d 7800 white cells, and after another six weeks was 4,350,000 per c.mm., 79 per cent. hæmoglobin, it the average size of the red cells was not increased. owever, she did not show a gain of strength commensurate with the improvement in the blood picture, d in November, 1931, profuse slumber sweats broke t over the chest, followed by tingling in the fingers the right hand and difficulty in walking. Within fortnight the characteristic glove and stocking æsthesia and ataxic gait of subacute combined generation of the cord were present.

There was sensory loss to light touch and pain extending the right arm to the elbow and in the left arm to the ist, and extending on to the trunk on the right upper orax. There was also sensory loss on the right leg to the lf and on the left leg to the ankle, also loss of vibration ase in both legs. There was intense pain on pressure in right upper arm. Astereognosis was complete in both nds, and loss of kinæsthetic sense in both arms and legs l to complete incoördination of movements. The kneeks were exaggerated on both sides, the plantar reflex was xor on the left, and ? extensor on the right. The abdonal reflexes were obtained with difficulty. The patient uld not walk without holding on for support, and then ly with an unsteady, spastic gait. Rombergism was so arked that she collapsed on to the floor on shutting her es. The sphincters were not affected. There was some iscular wasting of the arm and leg muscles, but power is fairly good except in the right arm, although the tient had been in bed for the anæmia for three months fore the onset of the disease. There were no trophic anges, but a bluish pigmentation of the skin of the lower domen was noticed. Cranial nerves were normal, but ere was a slight degree of verbal aphasia.

Treatment with intravenous arsenic had to be andoned owing to intolerance, and substitution of w liver for the extract effected little change in er condition after a month. At the beginning of ebruary, 1932, she was put on grs. 150 iron (as land's pill) daily,[1] and ¼ lb. raw liver twice weekly.

After two weeks sensation had returned in the left arm id in all but the fingers of the right arm. She could write, hich ability she had completely lost. Astereognosis and coördination in the hands disappeared, the pain was lieved, but the cold feeling persisted. The gait was still ery unsatisfactory, and Rombergism was present. At the eginning of the fourth week of treatment the patient ained control of her leg movements almost suddenly, and an now walk without support and even toe to heel. ombergism has disappeared.

The only signs of subacute combined degeneration now persisting are the slumber sweats, some anæsthesia of the terminal phalanges of three digits, and deficient vibration sense in the left leg. Meanwhile the erythrocyte count has fallen to 3,400,000 and the colour-index risen to 1·3; so the liver has been increased to ½ lb. daily.

A CASE OF UNDULANT FEVER

SIMULATING SUBACUTE CHOLECYSTITIS.

BY D. S. FAIRWEATHER, M.B., M.R.C.P. EDIN.,
HON. ASSISTANT PHYSICIAN TO BLACKBURN AND EAST LANCS. ROYAL INFIRMARY.

CASES of undulant fever still continue to attract the attention of increasing numbers of clinicians, and the latest extensive survey[1] of the varied manifestations of the disease suggests that these are protean. In this report by Hardy and his colleagues of 375 cases which occurred in the single State of Iowa, mention is made of the different diagnoses proffered before the actual cause of the conditions was discovered. Among the erroneous diagnoses were typhoid fever, influenza, tuberculosis, cardiovascular conditions, diseases of the genito-urinary system, and abdominal disorders. It is stated that Simpson[1 2] had a record of twelve appendicectomies and two cholecystectomies performed on cases of undulant fever.

The interest of the case under discussion lies in the full and intelligent description which the patient was able to give of her symptoms, and also in the fact that, in the hunt for the cause of the disease, the gall-bladder seemed to be the most likely focus of infection and a surgeon was called in for his opinion on the advisability of operation.

REPORT OF CASE.

The patient was a farmer's wife aged 30 years, who had had two children, the first, three years ago and the second, one year ago. She consulted me at my rooms at the end of January, 1931. Apologetically, she complained that she had a collection of minor ailments, no one of which in itself was enough to make her seek medical aid.

She had contracted a ringworm on the left forearm two or three weeks before Christmas which had healed, but which had recurred on the outbreak of a cold. Associated with the cold, a dry barking cough had developed about New Year's Day and had brought on vomiting. She further complained of anorexia, and of sweats in the morning from 3 to 6 A.M., which made her far too uncomfortable to sleep. She had noticed that on Christmas Day she had "felt off form and unable to eat her plum-pudding." By New Year's Day she was having "shivering fits" after midday dinner and attacks of goose-flesh, which would continue for the rest of the day if she left the fire, though not if she kept busy at her housework. The shivering attacks would last about half an hour, and as they passed off she began to feel hotter.

Her temperature on the first day of examination was 101° F. and her pulse-rate 96. She was accordingly sent to bed, and very soon her cough disappeared, though she developed a sore-throat. The fauces were a little inflamed, though not enough to account for the temperature. She continued to have occasional rigors about 2 to 3 A.M., and the association with cutis anserina and digestive disturbances —such as wind, occasional vomiting, feelings of vague abdominal discomfort, aching pains in the back, along with very definite tenderness and hyperæsthesia over the gall-bladder and to a lesser extent around McBurney's point—suggested the possibility of a subacute cholecystitis. The opinion of a surgeon was accordingly sought; while unable to give an alternative diagnosis, he thought that, in the absence of acute pain and greater constitutional disturbance, operation was not advisable. In the light of subsequent events, one must assume that the tenderness was due to a mild inflammatory reaction set up by the presence of organisms in the gall-bladder, as this is one of the places in which the organisms flourish.

Further questioning gave very little help, though there had been diarrhœa, about one day a week, without alternating constipation. The motions had been light brown in colour and rather offensive. The heavy sweats had been rather offensive and strong in odour at the beginning of the illness, though not latterly. Before the patient came to bed the tongue had been dirty grey colour and there had been a bad taste in the mouth and foul breath, though at the time of the first examination nothing abnormal was noted. There had been frontal headaches, especially on awakening in the morning, for some weeks previously. On the whole, sleep was not much disturbed, though she had a tendency to sleep lightly and to awaken early in the morning. Menses were normal.

Rash.—About the beginning of February the patient had noticed on the backs of the hands colourless raised-up spots; these lasted two or three days and then disappeared. They did not cause itching.

Beyond an occasional trace of albumin, no abnormalities were detected in the *urine*. There were a few scattered râles in the *chest*, but no other indications of morbidity.

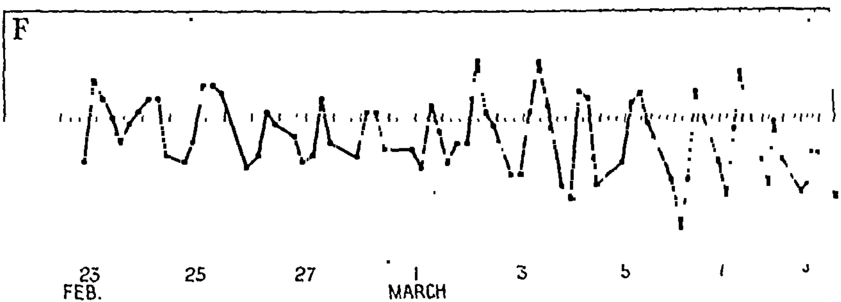
The *spleen* was felt to be soft and was tender to the touch. Although it was definitely enlarged, deliberate examination had to be carried out to detect the enlargement.

Blood.—On Feb. 25th a white blood count showed 8000 cells per c.mm. No differential count was made.

On Feb. 26th a bacteriological report on the blood showed negative agglutination to the enteric group. Agglutination to *Bacillus abortus* Bang was obtained in a titre of 1 in 1280 at 55° C. after 18 hours. The organisms were not isolated from urine or blood, and unfortunately, owing to the difficulties of distance, I was unable to get a further specimen of blood for direct inoculation at the height of the fever.

Temperature.—The chief point of interest in the four-hourly temperature chart (Fig. 1) is the daily maximal temperature appearing round about 2 P.M. in the early part of the illness, but at about 6 P.M. as the illness developed. This feature is mentioned in the Ministry of Health Report by Dalrymple-Champneys,[3] who states that in Mediterranean fever "the fever is usually of the remittent type, the rise beginning (according to Hughes) about 11 A.M., attaining its maximum between 2 and 3 P.M. and then falling, reaching normal about 10 P.M. or 11 P.M. or later, the fall being accompanied by profuse perspiration." It will be seen from the chart (Fig. 1) that, generally speaking, in the present case the temperature did not attain its minimum until 6 to 10 A.M. The total duration of the fever (Fig. 2) was probably about 90 days, though an occasional elevation of temperature was noted in the evening after the expiry of that length of time.

FIG. 1.



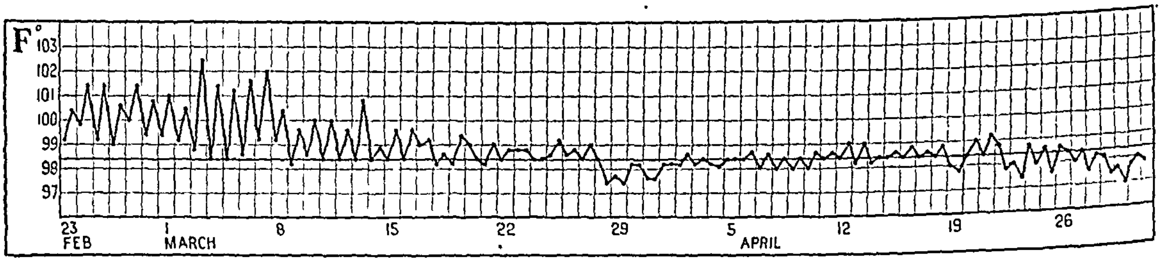
Part of four-hourly temperature chart, showing time of day when temperature was highest.

The pulse-rate varied between 80 and 100 in the initial stages of the illness.

Course of Illness.—On March 13th the patient complained for the first time of joint pains. The left shoulder began to ache during the day, and this led to difficulty in moving. The pains also affected the elbow. A few red spots appeared on the abdomen, situated about two inches from each other. They were very itchy and not raised up. On March 20th a rash broke out on the foot. The feet and hands itched and burned all through the night. The rash spread up the front of the leg and up both buttocks, and appeared on the back of the right arm and elbow and on the neck below the mandible. It was evident on the soles of the feet, the palms of the hands, and between the fingers. Around the joints it came as big red blotches, while in other places it consisted of reddish spots, about the size of a lentil, more like the rash of rubella than anything else. The spots were slightly raised, and disappeared on pressure.

On March 22nd the rash completely covered the whole body, and on the following day it began to fade from the places first affected. It was almost gone two days later, except for the flexures of the elbows. On March 30th the spleen was just palpable. The patient was now getting up. On April 13th the spleen was neither palpable nor tender.

FIG. 2.



Morning and evening temperature chart.

ORIGIN OF INFECTION.

On inquiring from the farmer (the patient's husband) I learned that there had been an epidemic contagious abortion among five of the cattle. : first cow “ picked its calf ” (to use the farmer’s ression) in September, seven weeks before it ; due to calve. The calf was dead, but the veterinary geon inoculated the cow, which the farmer retained. : second one was delivered about the middle of ember, and the calf survived. The cow was ked for a fortnight and then sold. As the patient ; in the habit of drinking fairly large quantities nilk, it seems most likely that this cow was the rce of infection, as the symptoms were first noted Christmas Day; this fits in with the incubation iod of six to twenty days (Bassett-Smith [4]). The er cows aborted after the onset of the patient’s ess. According to Dalrymple-Champneys [5] the jority of actual abortions occur between the fifth seventh months of pregnancy, though quite n it is not noticed, as the animal’s general health isually quite unaffected. The farmer stated that condition showed itself in his cows by the urrence of premature labour with a tendency the placenta to be retained; this was likely to be owed by a discharge for 14 to 21 days (instead of) 14), offensive and dirty yellowish-looking, associated with a diminution or complete absence of ation.

SUMMARY.

his case was characterised by: (1) An irregular exia attaining its daily maximum height at about .M., associated with a pulse-rate not elevated in portion to the fever and accompanied by rigors. Constitutional disturbance far less severe than ld be expected from the height of the fever. Definite tenderness over the gall-bladder area, to a lesser extent in the right iliac fossa. Definite splenic enlargement and tenderness. Definite history of contagious abortion in cattle the farm. (6) Report of agglutination in titres up 1 in 1280 dilution against *B. abortus* Bang at C. (7) Indefinite symptoms and signs referable the respiratory tract. (8) Delayed appearance of it pains and, except for a fleeting eruption towards beginning of the second month of the illness, rked delay in the appearance of a rash.

wish to express my indebtedness to the director staff of the Public Health Laboratory, Manchester, carrying out the agglutination reactions.

NDER RIB-CARTILAGE AS A SIGN OF CHOLECYSTITIS.

D. W. CARMALT-JONES, D.M. OXF., F.R.C.P. LOND.,
OFESSOR OF SYSTEMATIC MEDICINE IN THE UNIVERSITY OF OTAGO, N.Z., AND PHYSICIAN TO THE DUNEDIN HOSPITAL.

CHOLECYSTITIS is stated by Hurst [1] to be the mmonest of all chronic abdominal disorders; it is rtainly common in New Zealand, and I recently alysed 100 cases admitted within two years to a spital of 300 beds.

Some years ago, in examining a case of it my ger-tips accidentally came into abrupt contact with e patient’s rib-cartilage bounding the right hypo- ondrium, which induced a sharp flinch of pain, and on closer examination I found a tender spot upon the eighth right costal cartilage, on its lower edge (not its anterior surface), which could have been found by approaching the patient from behind and hooking one’s right-hand fingers round the costal margin.

Since then I have sought for it in every abdomen that I have examined, and I have found it repeatedly in cases of cholecystitis, with or without gall-stones; of course, the great majority of such cases have gall-stones. The sign is sought for with the hand flat on the upper abdomen; the third finger-tip is brought into firm contact with the costal margin, inch by inch along its whole length from without inwards, beginning on the left side, saying nothing and watching the patient’s face. Occasionally in cases of gastric ulcer there is a similar but slighter area of tenderness on the left rib margin, but it is inconstant. On the right, in a case of cholecystitis, a single tender spot, indicated by the patient’s expression, is found, generally on the eighth rib edge, sometimes a little higher or lower, and just covered by the finger-tip. Occasionally, but by no means always, the skin of the whole eighth dorsal segment on the same side is hyperalgesic to pin-prick. I believe this tender spot to be quite as dependable in the diagnosis of cholecystitis as is McBurney’s point in appendicitis.

In some cases of cholecystitis it is continually present, in others it comes and goes, but is usually to be found when any degree of colic is in progress and for some days after, even in persons who do not always show it. It is not invariably present; it is not a sine qua non of cholecystitis; I have failed to find it in a few cases with a positive Graham’s test, in which gall-stones were present at operation.

In a series of 20 cases, analysed for another paper, the following results were obtained :—

		Tenderness.	No tenderness.
Previously operated upon for cholecystitis	5	5	—
No operation, symptoms of cholecystitis	4	3	1
Cholecystitis and gall-stones at operation	6	6	—
Cholecystitis, *no stones at operation* ..	5	4	1

I do not find that writers on the gall-bladder describe this sign: Graham, Cole, Copher, and Moore [2] mention “a manœuvre first described by J. B. Murphy, a sudden jab of the fingers under the right costal margin just as the patient has completed a deep inspiration . . . will elicit tenderness.” This, I take it, is meant to exert pressure on the gall-bladder, but no “sudden jab” is required on the cartilage. Hurst and Stewart [3] state under “differential diagnosis” that “tenderness of the gall-bladder is increased or only present when a deep inspiration carries the gall-bladder sufficiently far below the costal margin to bring it into contact with the fingers,” which is probably seeking for Murphy’s sign. Walton [4] states that “occasionally there may be slight tenderness in the epigastrium or over the gall-bladder.” Griffiths [5] writes of “tenderness below the tip of the ninth right costal cartilage,” and Rolleston and McNee [6] write of “tenderness over the upper right quadrant of the abdomen which becomes more localised and more intense at the so-called biliary point below the tip of the ninth costal cartilage. Cutaneous hyperæsthesia may be present in the eighth and ninth dorsal segments.” I can, however, find no account of tenderness of the costal margin, of the existence of which I have none the less convinced various sceptical colleagues.

The precise significance, the mechanism of the over the gall-bladder and to a lesser extent around McBurney's point—suggested the possibility of a subacute cholecystitis. The opinion of a surgeon was accordingly sought; while unable to give an alternative diagnosis, he thought that, in the absence of acute pain and greater constitutional disturbance, operation was not advisable. In the light of subsequent events, one must assume that the tenderness was due to a mild inflammatory reaction set up by the presence of organisms in the gall-bladder, as this is one of the places in which the organisms flourish.

Further questioning gave very little help, though there had been diarrhœa, about one day a week, without alternating constipation. The motions had been light brown in colour and rather offensive. The heavy sweats had been rather offensive and strong in odour at the beginning of the illness, though not latterly. Before the patient came to bed the tongue had been dirty grey colour and there had been a bad taste in the mouth and foul breath, though at the time of the first examination nothing abnormal was noted. There had been frontal headaches, especially on awakening in the morning, for some weeks previously. On the whole, sleep was not much disturbed, though she had a tendency to sleep lightly and to awaken early in the morning. Menses were normal.

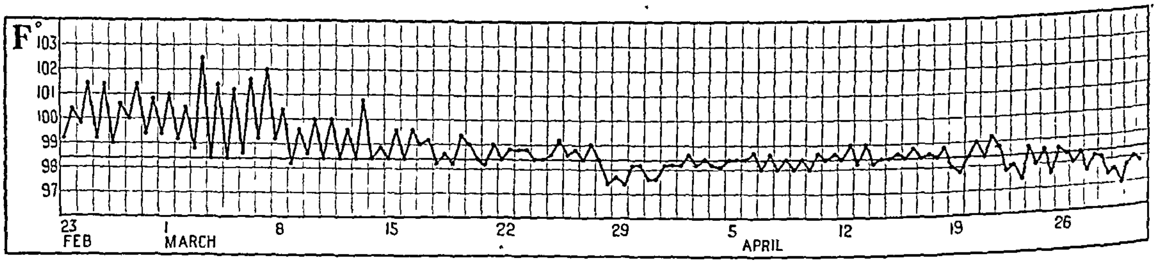
Rash.—About the beginning of February the patient had noticed on the backs of the hands colourless raised-up spots; these lasted two or three days and then disappeared. They did not cause itching.

Beyond an occasional trace of albumin, no abnormalities were detected in the *urine*. There were a few scattered râles in the *chest*, but no other indications of morbidity.

The *spleen* was felt to be soft and was tender to the touch. Although it was definitely enlarged, deliberate examination had to be carried out to detect the enlargement.

Blood.—On Feb. 25th a white blood count showed 8000 cells per c.mm. No differential count was made.

FIG. 2.



Morning and evening temperature chart.

On Feb. 26th a bacteriological report on the blood showed negative agglutination to the enteric group. Agglutination to *Bacillus abortus* Bang was obtained in a titre of 1 in 1280 at 55° C. after 18 hours. The organisms were not isolated from urine or blood, and unfortunately, owing to the difficulties of distance, I was unable to get a further specimen of blood for direct inoculation at the height of the fever.

Temperature.—The chief point of interest in the four-hourly temperature chart (Fig. 1) is the daily maximal temperature appearing round about 2 P.M. in the early part of the illness, but at about 6 P.M. as the illness developed. This feature is mentioned in the Ministry of Health Report by Dalrymple-Champneys,[3] who states that in Mediterranean fever "the fever is usually of the remittent type, the rise beginning (according to Hughes) about 11 A.M., attaining its maximum between 2 and 3 P.M. and then falling, reaching normal about 10 P.M. or 11 P.M. or later, the fall being accompanied by profuse perspiration." It will be seen from the chart (Fig. 1) that, generally speaking, in the present case the temperature did not attain its minimum until 6 to 10 A.M. The total duration of the fever (Fig. 2) was probably about 90 days, though an occasional elevation of temperature was noted in the evening after the expiry of that length of time.

TENDER RIB-CARTILAGE AS A SIGN OF CHOLECYSTITIS.

By D. W. Carmalt-Jones, D.M. Oxf., F.R.C.P. Lond.,

PROFESSOR OF SYSTEMATIC MEDICINE IN THE UNIVERSITY OF OTAGO, N.Z., AND PHYSICIAN TO THE DUNEDIN HOSPITAL.

Cholecystitis is stated by Hurst[1] to be the commonest of all chronic abdominal disorders; it is certainly common in New Zealand, and I recently analysed 100 cases admitted within two years to a hospital of 300 beds.

Some years ago, in examining a case of it my finger-tips accidentally came into abrupt contact with the patient's rib-cartilage bounding the right hypochondrium, which induced a sharp flinch of pain, and on closer examination I found a tender spot upon the eighth right costal cartilage, on its lower edge (not its anterior surface), which could have been found by approaching the patient from behind and hooking one's right-hand fingers round the costal margin.

Since then I have sought for it in every abdomen that I have examined, and I have found it repeatedly in cases of cholecystitis, with or without gall-stones; of course, the great majority of such cases have gall-stones. The sign is sought for with the hand flat on the upper abdomen; the third finger-tip is brought into firm contact with the costal margin. inch by inch along its whole length from without inwards, beginning on the left side, saying nothing and watching the patient's face. Occasionally in cases of gastric ulcer there is a similar but slighter area of tenderness on the left rib margin, but it is inconstant. On the right, in a case of cholecystitis, a single tender spot, indicated by the patient's expression, is found, generally on the eighth rib edge, sometimes a little higher or lower, and just covered by the finger-tip. Occasionally, but by no means always, the skin of the whole eighth dorsal segment on the same side is hyperalgesic to pin-prick. I believe this tender spot to be quite as dependable in the diagnosis of cholecystitis as is McBurney's point in appendicitis.

In some cases of cholecystitis it is continually present, in others it comes and goes, but is usually to be found when any degree of colic is in progress and for some days after, even in persons who do not always show it. It is not invariably present; it is not a sine qua non of cholecystitis; I have failed to find it in a few cases with a positive Graham's test, in which gall-stones were present at operation.

In a series of 20 cases, analysed for another paper, the following results were obtained:—

		Tenderness.	No tenderness.
Previously operated upon for cholecystitis	5	5	—
No operation, symptoms of cholecystitis	4	3	1
Cholecystitis and gall-stones at operation	6	6	—
Cholecystitis, no stones at operation	5	4	1

I do not find that writers on the gall-bladder describe this sign: Graham, Cole, Copher, and Moore[2] mention "a manœuvre first described by J. B. Murphy, a sudden jab of the fingers under the right costal margin just as the patient has completed a deep inspiration . . . will elicit tenderness." This, I take it, is meant to exert pressure on the gall-bladder, but no "sudden jab" is required on the cartilage. Hurst and Stewart[3] state under "differential diagnosis" that "tenderness of the gall-bladder is increased or only present when a deep inspiration carries the gall-bladder sufficiently far below the costal margin to bring it into contact with the fingers," which is probably seeking for Murphy's sign. Walton[4] states that "occasionally there may be slight tenderness in the epigastrium or over the gall-bladder." Griffiths[5] writes of "tenderness below the tip of the ninth right costal cartilage," and Rolleston and McNee[6] write of "tenderness over the upper right quadrant. of the abdomen which becomes more localised and more intense at the so-called biliary point below the tip of the ninth costal cartilage. Cutaneous hyperæsthesia may be present in the eighth and ninth dorsal segments." I can, however, find no account of tenderness of the costal margin, of the existence of which I have none the less convinced various sceptical colleagues.

The precise significance, the mechanism of the tenderness, is a matter upon which one who is only a clinical observer can but speculate. I have to confess that I have had a few cases of apparently typical biliary colic, with a tender cartilage, which came to operation and that then a normal gall-bladder was found.

The gall-bladder is a hollow viscus, and like the other hollow viscera pain arising from it is caused only by some increase of tension within it. It is presumably insensitive to trauma, and hepatic colic is not due to the scratching of a sensitive surface by a gall-stone, but to spasmodic and ineffectual contraction of the viscus, caused, it may be, by an incoördination between the fundus and the sphincter of Oddi through disturbance of the harmonious coöperation of the vagus and sympathetic.

Bain [7] states that the nerve-supply of the gall-bladder consists of the vagus and of fibres from the sympathetic, 6 D to 1 L. Experimentally, slight stimulation of the vagus causes the fundus to contract and the sphincter of Oddi to relax, and this may be assumed to be what occurs when the gall-bladder empties in health. But under strong stimulation of the vagus both fundus and sphincter go into spasm, so that the contraction of the fundus is ineffectual—the condition which induces visceral pain. It may be that biliary colic depends on such stimulus of the vagus. I would suggest that spasm of the sphincter of Oddi, which is believed to be controlled by the sympathetic, induces this tender spot on the body wall, and sometimes hyperalgesia of a whole segment in the area of [illegible] ic innervation. The cases found [illegible] may be due to reflex spasm induced by a focus of irritation elsewhere, or to another cause; spasm of the gall-bladder may possibly be an allergic manifestation.

Graham and his colleagues [8] remark that intestinal allergy is probably rather frequently confused with cholecystitis, but this has received "almost no mention."[2] I believe that some of the negative cases are due to intestinal allergy; this question I am discussing in another paper.

I believe, however, that tenderness of the right costal margin, in the neighbourhood of the eighth costal cartilage, is a valuable sign of disturbed function of the gall-bladder, which is in most cases due to cholecystitis and gall-stones.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE.

COMBINED SECTIONS OF UROLOGY AND OBSTETRICS.

AT a combined meeting of these sections on March 10th, Mr. R. OGIER WARD, the President of the Section of Urology, being in the chair, the subject of discussion was

Frequency of Micturition in Women.

Mr. G. E. NELIGAN said mostly the cause of the frequency was easy to diagnose and the treatment was well established, though in some cases the outlook from the start was hopeless. He enumerated the causes of over-secretion of the kidneys, which might occur: (1) in the later stages of chronic nephritis, when it was due either to acute nephritis of primary character or to hyperpiesis—the history, physical signs, and the presence of albumin and casts in the urine supplied the clue; (2) in the presence of congenital cystic kidneys, where a palpable tumour might be felt and pyelography would aid diagnosis; (3) in diabetes mellitus; (4) in renal calculus, where the history and X rays gave the diagnosis; (5) in renal tuberculosis, pyelocystitis, and pyelonephritis; and (6) in functional polyuria. After mentioning briefly causes arising in the bladder itself, such as calculi, foreign bodies, and carcinoma, and causes of frequency outside the bladder, including pressure of the pregnant uterus, or pelvic tumours, as fibroids or ovarian cysts, Mr. Neligan spoke in more detail on pyelonephritis and functional polyuria.

Pyelocystitis and pyelonephritis.—Usually these cases were readily diagnosed, and readily responded to treatment. It was still not sufficiently recognised that frequent and large doses of alkalis should be given, and that it was not advisable to stop giving potassium citrate as soon as symptoms and temperature subsided. He himself prescribed pot. cit. ʒ i. two-hourly until the urine was alkaline, and then gave the drug in sufficient doses to keep the urine alkaline for a fortnight. The difficult cases were the mild ones, symptoms being confined to frequency and pain on micturition. Basal cystitis was usually present and frequently both kidneys were infected. Every patient who had persistent cystitis should have the urine from each kidney cultured, should be examined radiographically and have a pyelogram taken, so as to exclude such complications as calculi. The bladder condition could not be cleared up until the kidneys were well. Patients with pyelocystitis should be impressed with the fact that the three cardinal sins of life were catching cold, drinking too little fluid, and allowing constipation to become established. This applied especially to women who feared that copious drinking of water would make them fat. Diet also was important; often these women lived on slops and were half-starved.

Functional polyuria.—Patients with functional polyuria usually complained of great frequency during the day, but slept peacefully through the night. Their attention was fixed on their bladders and hence their social activities were restricted; a railway journey, however short, in a carriage without a lavatory became an agony. Yet they could take a long motor journey without inconvenience if their minds were occupied with a subject of interest. Mr. Neligan felt sure the problem was one of nervous over-secretion of the kidney, because each time these patients urinated they passed a good quantity. Both sexes suffered from it in times of unusual emotional stress, such as during an examination, or when under heavy fire in warfare. In chronic cases the polyuria still continued when the stress was over. In women who had taken sexual risks and were suffering from gonophobic polyuria ceased when they were reassured on this point. Treatment of functional polyuria was difficult and often hopeless. The main requirement was to give an exhaustive mination in order to be able to assure the patient the absence of organic disease. Many patients e impressed if it was explained to them that the ney over-secretion was due to worry.

Ir. **Victor Bonney** said that frequency might (1) due to disease or abnormality of the urinary ct or of the genital organs, or of neighbouring struc- es; or (2) of purely nervous origin. The last group ild be further divided into those associated with excessive production of urine, and those lacking h excessive production. In the first of these groups hing was wrong with the bladder, the frequency ng merely the result of the excessive kidney retion. In the second group the nervous chanism was at fault. It could be taken as a rule it frequency which woke the patient at night d compelled evacuation had a physical basis, ile if sleep was uninterrupted the case was probably e to functional disturbance. The next main tegory was of cases in which the frequency was e to vagino-vesical displacement. One of the most mmon forms of urinary trouble in women was that which Mr. Comyns Berkeley and himself had awn attention and which had been termed "stress continence" by Mr. Eardley Holland. It occurred women who had borne children, but was not erative until a number of years after the birth. was a mistake to attribute it to cystocele. These omen voided a sudden jet of urine on coughing or eezing, or on performing any other sudden act. true cystocele consisted of a hammocking of the ginal wall accompanied by a pouch in the base of ie bladder, and in excessive degrees it might be ecessary for the patient to push the cystocele up ith her finger before the bladder would act. Stress continence was accompanied by a descent of the wer end of the vagina away from its attachment the subpubic angle, and this involved also the lock of tissue in which the urethra ran and which he speaker had termed the peri-urethral wedge. n the female there was no collection of fibres at the ladder neck which could be called a true sphincter. Instead there was a sphincteric mechanism as he had pointed out in a previous paper. A pessary in these cases was useless. They could be cured by an operation which tautened the sphincteric mechanism. In a few cases ventrofixation of the bladder might be needed. In stress incontinence the escape of urine was quite involuntary, and was not preceded by the urge to micturate, but in what he termed "precipitate micturition" and "urge incontinence" the desire to micturate was so sudden and violent that unless the patient could instantly relieve herself incontinence occurred. The urine in these cases showed no changes pointing to bladder inflammation, and the cystoscope showed no more, in the speaker's experience, than a slight blush at the base of the bladder. The condition was evidently due to a hypersensitisation of sensory nerve-endings or perhaps some vasomotor instability of the vessels in that region. In conclusion, Mr. Bonney spoke of frequency due to urethral carunculosis. For this condition when intractably recurrent he had obtained relief by lengthening the urethra by an operation, the technique of which he described.

Miss **G. M. Sandes** said that a comprehensive view of the occurrence of frequency of micturition in women would not be obtained until women had been educated to recognise that frequency was not normal, and should be reported to a doctor. When frequency occurred in patients suffering from venereal diseases it was usually associated with pain; it was very common at the onset of gonorrhœa. Some patients suffered from frequency before discharge occurred. Of hospital gonorrhœa patients she found that 85 per cent.—chiefly girls of 16 to 25 years—had frequency with pain. A young girl might not show diminished frequency until after many weeks in hospital. In older women acute urethritis either cleared up fairly rapidly or became chronic. Many women thought it was the common lot to have a vaginal discharge, and this belief accounted for the fact that many cases of gonorrhœa were not diagnosed until salpingitis supervened. A non-gonorrhœal form of urethritis usually proved very intractable; here frequency was apt to be continuous. On culturing the urine, diphtheroids were grown. Massive doses of alkali and weekly instillation of glycerin was the treatment indicated. The condition was found commonly in dancers and gymnasts. Gumma of the bladder caused frequency, and it was a marked symptom in tabetic women. If it was untreated, overflow incontinence resulted. One group of cases with frequency included those who had had an operation for prolapse of the uterus; the calls could not be said to be due to a nervous condition. Examination often revealed a small pouch beyond the internal meatus, and this contained residual urine.

Mr. **Duncan M. Morrison** spoke particularly of neurosis of the bladder, and chronic glandular lymphoid cystitis. In cases of neurosis, examination was usually negative, but the patients who were usually very nervous and irritable complained of marked frequency and urgency, with a dull aching pain in the suprapubic region and in either inguinal region. Careful routine examination showed a contracted urethra and bladder neck, so that the capacity of the bladder was reduced. In some cases an indolent submucous ulcer could be seen, when the urethra was treated by argyrol instillations and gradual dilatation, and at a later stage silver nitrate solution of gradually increasing strength. The ulcer should be touched with 10 per cent. silver nitrate. Failing response, radical resection must be done. Chronic granular lymphoid cystitis occasionally occurred in girls who had marked diurnal and nocturnal frequency, urination usually being precipitate, while the terminal tenesmus might last minutes. Bearing-down pains in the perineum might extend to the clitoris. These women were mentally depressed, and many of them thought they had cancer. The organism most often found was *B. coli*. With the cystoscope a diffuse granular injection with discrete, raised pink nodules over the trigone and the bladder neck was usually seen. Argyrol of 2 per cent. strength should be used, increasing to 10 per cent.

Mr. **H. P. Winsbury White** said that about 75 per cent. of the women he examined had frequency of micturition, and the cause was generally in the pelvis. The symptom could be caused by trifling inflammations of urethra and cervix uteri. A cervical erosion, with or without a muco-purulent discharge, or small granulomata projecting from the os sufficed to produce polyuria. In quite a number of long-standing cases a chronic infection of the urinary tract with *B. coli* was found. Cystitis might be present, but very little in the urine to account for it. In 12 cases in a series of 215 a urethral stricture was present; 53 per cent. of his cases with cervical conditions showed organisms in the urine.

The **Chairman** insisted on the need for routine culture of the urine in these cases. Unless a patient had pus in the urine she could not be said to have cystitis. In some cases the character of the urine coming down from the kidney was such that it caused frequency by irritating the bladder. In a number of other cases he felt sure there was no irritation of the bladder itself. One could do a good deal for functional cases by encouragement. When these patients attended hospital and their attention was taken off their trouble they were often surprised to find how long they had gone without passing water; if they then passed, say, 18 oz. it could be made clear to them that their bladder capacity was adequate, and that if they ceased to worry their trouble would probably disappear. A group of patients was seen, chiefly among old people, whose bladder was always greatly congested, and who always suffered from frequency, with much pain. In these the vesical capacity was small. It was probably due to a long-past infection and was difficult to treat.

SECTION OF TROPICAL DISEASES AND PARASITOLOGY.

AT a meeting of this section on March 3rd Dr. CLEMENT CHESTERMAN read a paper on the training and employment of

African Natives as Medical Assistants.

He pointed out that Africa, with one-fifth of the land surface of the globe, contained but one-thirteenth of the world's population. On the West Coast there were between 25 and 30 people to the square mile, whereas in Central Africa there were but 10 or 15, although it was certain these areas where the population was the greatest asset could support ten times that number. The difficulty of providing a medical and sanitary service for rural Africa was very great, not only geographically, but on account of superstition and certain native beliefs and customs, and our best efforts were liable to be looked upon as a kind of persecution. The only way to solve the problem and avoid misunderstanding was through coöperation with the people themselves. He quoted the late Sir Gordon Guggisberg's high opinion of the educability of the native and stated that he believed that the so-called arrested development, where it was observable, was probably but a defensive mechanism of the normal youth against an education ill-suited to his adult life and environment. Simple medical education and practice was eminently suited to his needs and capacities, but for the very reason that it was apt to raise the youth high above the general level of culture and public opinion with regard to disease, he was correspondingly tempted to lose his balance. For some generations therefore it was advisable for his own sake and for others that he should serve under supervision and not as a private practitioner.

Dr. Chesterman outlined the present practice in Sierra Leone, the Gold Coast, Nigeria, the Sudan, Uganda, Tanganyika Territory, Nyasaland, French West Africa, and the Belgian Congo, dealing in more detail with efforts in which he had been associated for some years at a mission hospital at Yakusu near Stanleyville in the latter colony. The most important equipment for a training school, he said, was first patients, second patients, and third, more patients. For the teaching staff the equipment was the same, spelt with a "ce." The hospital should be constructed to allow of the easy supervision of all departments by a limited staff, and for that reason a central administration block was preferable to scattered buildings.

In describing the various policies and practices he offered some suggestions for the consideration of those who were responsible for the framing of colonial policy in this matter. An A.D.M.S. medical education should be appointed to unify training, text-books, and examinations, and be responsible for the posting and promotion of medical assistants, who gave better service if the personal touch was maintained. Medical officers interested in such work should be encouraged to believe that in that career they would receive promotion to the teaching posts of the higher institutions and administrative posts. Although higher medical education in Africa with a view to the replacement of European doctors was a proper policy where the general educational level demanded it, yet the formation of a large number of more humble and less expensive native "general practitioners" was the only solution to the rural problem. These could best be trained in rural hospitals, a three years' course sufficing, with practice and theory combined from the start, and subsequently employed in dispensaries depending on their alma mater.

Dr. Chesterman hoped that the new spirit of coöperation between governments and missions might be extended into the realm of rural hygiene, and that many of his fraternity might be stimulated to greater efforts; for all who had faced the problem on the field were agreed that although a little knowledge is a dangerous thing, a lot of ignorance was even more dangerous.

HARLEY MEDICAL SOCIETY.

AT the inaugural meeting of this society held on March 10th, the chair was first taken by Dr. MORELAND MCCREA, who explained the origin of the society as an attempt to foster the scientific spirit among members of the Medical Group of the new London Clinic and Nursing Home. These members, he said, essentially constituted a club and not a company, and they realised that without scientific ideals medicine would soon become a trade. Sir LENTHAL CHEATLE then took the chair.

Mr. LOCKHART MUMMERY read a paper on the

Origin of Tumours.

He said that it had long been evident that any explanation of the origin of tumours must account for their rapidity of growth. He was convinced that the secret of tumour formation must be approached by the study of normal cells. No complete theory had satisfactorily explained why certain cells occasionally behaved abnormally by growing at a faster rate than the normal rate of the tissue to which they belonged. He enumerated the following established facts about tumours as facts which any ætiological theory would have to explain: (1) Tumour cells grew by their own division and not by converting neighbouring cells into tumour cells. (2) The tumour cell was specific to its original character wherever it might be. (3) Tumour cells were species-specific. (4) A very great many different kinds of tumour were to be found in any one species, even tumours growing from the same kind of tissue showed great differences, and two identical tumours were seldom met. (5) Tumours could be produced by a at many different agents and these agents had factor in common. (6) Every tumour showed a ent period at the beginning of its development, d this latency did not depend on the age of the ject.

The tumour cell was characterised by an alteration its behaviour, not in its apparent structure. obably all cells of the body underwent mitosis at tain times, to replace worn-out cells, but the rate reproduction varied considerably, and the process d not yet been observed in those tissues where it ly occurred at long intervals. There was a beautily exact adjustment to the requirements of the ne cells themselves, and the primary controlling tor must be within the cells. Certainly, the haviour of any cell might be profoundly modified environmental factors, such as hormones, but the sponse to these factors was fixed, and determined its inherent controlling mechanism, inherited m the original germ cells. If a cell or group of lls was found to behave in a radically different anner from that of its neighbours, then some dical change must have taken place in its nucleus

THE GENE THEORY.

Every human cell contained 24 pairs of chromosomes thin its nucleus, and each chromosome contained a st and unknown number of genes. These genes re the controlling factor in the cell's behaviour. e genes in the fertilised germ cell controlled the te and behaviour of all the daughter cells and ensured at every daughter cell should breed true to the rent. This was equally true of somatic cells, and the recognition of this fact lay the explanation of mours. Studies of the germ cell had shown that anges in the nature of the genes could be brought out by extrinsic influences; these mutations were herited by all daughter cells. Most biologists lieved that accidental gene mutations had been ry largely responsible for the evolution of new ecies. If a gene mutation could occur in a germ ll, it could also occur in a somatic cell, with similar sults. The suggestion that tumours might be due mutation in the nucleus of the somatic cell had st been put forward, more than ten years ago, y a German zoologist, Theodor Boveri.

If the gene change produced in the cell was one for cessive reproduction, then a colony of excessively producing cells would soon form, and would all ntinue to breed true, and would increase at the pense of surrounding tissues. This mutation eory explained all the known facts about both ant and animal tumours; it was the missing piece the jigsaw puzzle. It explained why tumour cells ere specific to the tissue in which they arose, and hy they grew from their own cells and not by converting neighbouring cells into tumour cells. It also plained why there were so many different carcinoenic agents and such a great variety of tumours, nd the latent period in tumour formation. The heory was not susceptible to experimental proof, ut relied on logical deductions from observed acts.

There must be other mutations besides that for xcessive reproduction, and many diseases besides umours could probably be explained in this way: ome of the leukæmias, for instance. Melanotic nd keratotic changes in the skin—e.g., xeroderma igmentosum—were examples of mutation. Gene utation could be produced by very many agents, s had been shown by experiment; the agent was ssumed to cause an injury to a gene or group of genes. Obvious results of gene mutation would, however, be seen only exceptionally, as they would not be visible for several cell-generations, and adult cells reproduced but slowly. Skin cells were replaced more often than deeper cells, and changes in them were more obvious; therefore these changes were best known in skin epithelium.

The CHAIRMAN said that there were only two concrete theories before the world concerning the origin of tumours: the virus theory and the gene theory. The former might be incorporated in the latter. In Paget's disease of the nipple a deep carcinoma might arise in the terminal ducts and acini, in addition to the benign superficial condition in the epidermis or upper duct openings; this could be well explained by the gene theory, and he did not believe that it was due to transplantation.

DISCUSSION.

Dr. R. J. LUDFORD showed a series of lantern slides illustrating the gene theory. Chromosomes, he said, showed no structure, and the genes were postulated to explain observed phenomena; they were estimated to measure 20–77 μμ—far below the smallest thing that could be seen under the microscope. The human blood corpuscle measured 7500 μμ. Nevertheless the gene was a very living concept in biology at the present time, occupying much the same position as the atom in physics. The genes were assumed to be ranged in linear fashion—many hundreds of them to each chromosome—and at each cell division each chromosome split longitudinally, so that each daughter cell contained the same number of genes as the parent cell. It was postulated that in every cell of the human body there were 48 chromosomes, 24 of maternal and 24 of paternal origin, the chromosomes being regarded as the physical basis of heredity. The number of chromosomes in tumour cells varied considerably, but at each cell division the same number passed into each daughter cell. Sex was determined by the male germ cells, some of which contained "x" chromosomes and some "y" chromosomes. The female produced "x" cells only. In some cancer cells these special chromosomes could be recognised. Dr. Ludford illustrated the transmission of colour blindness and hæmophilia as gene mutations. It was difficult to see how a cell could retain malignant characteristics over a long period of years without some alteration in its mechanism. The gene theory seemed to offer the best explanation of the phenomena of the cancer cell, although it did not lead anywhere therapeutically. Further research should be directed to discovering some as yet unknown fundamental biological process in the malignant cell.

Dr. J. C. MOTTRAM said that the mutation theory had arisen from the discovery that X radiation could produce malignancy. Once a gene was altered, it was altered for ever, and this rule applied to the cancer cell; the Jensen rat sarcoma remained to-day exactly as it had been when it was first discovered. There was no real difference between a somatic and a genetic mutation. A mutation occurring very late in development would affect a single cell. If it was a change causing rapid division, a tumour would result; if it caused some other alteration, we should probably know nothing about it. He had tried inoculating irradiated cells into animals and had produced a tumour.

Dr. W. E. GYE stressed the hypothetical nature of the gene theory, which was not accepted by all biologists. Hypothesis was being heaped on hypothesis had pus in the urine she could not be said to have cystitis. In some cases the character of the urine coming down from the kidney was such that it caused frequency by irritating the bladder. In a number of other cases he felt sure there was no irritation of the bladder itself. One could do a good deal for functional cases by encouragement. When these patients attended hospital and their attention was taken off their trouble they were often surprised to find how long they had gone without passing water; if they then passed, say, 18 oz. it could be made clear to them that their bladder capacity was adequate, and that if they ceased to worry their trouble would probably disappear. A group of patients was seen, chiefly among old people, whose bladder was always greatly congested, and who always suffered from frequency, with much pain. In these the vesical capacity was small. It was probably due to a long-past infection and was difficult to treat.

SECTION OF TROPICAL DISEASES AND PARASITOLOGY.

AT a meeting of this section on March 3rd Dr. CLEMENT CHESTERMAN read a paper on the training and employment of

African Natives as Medical Assistants.

He pointed out that Africa, with one-fifth of the land surface of the globe, contained but one-thirteenth of the world's population. On the West Coast there were between 25 and 30 people to the square mile, whereas in Central Africa there were but 10 or 15, although it was certain these areas where the population was the greatest asset could support ten times that number. Mr. LOCKHART MUMMERY read a paper on the

Origin of Tumours.

He said that it had long been evident that any explanation of the origin of tumours must account for their rapidity of growth. He was convinced that the secret of tumour formation must be approached by the study of normal cells. No complete theory had satisfactorily explained why certain cells occasionally behaved abnormally by growing at a faster rate than the normal rate of the tissue to which they belonged. He enumerated the following established facts about tumours as facts which any ætiological theory would have to explain: (1) Tumour cells grew by their own division and not by converting neighbouring cells into tumour cells. (2) The tumour cell was specific to its original character wherever it might be. (3) Tumour cells were species-specific. (4) A very great many different kinds of tumour were to be found in any one species, even tumours growing from the same kind of tissue showed great differences, and two identical tumours were seldom met. (5) Tumours could be produced by a ntion and treatment which were only just being ciated. Acute glomerular nephritis and the ıg chronic condition were essentially infective gin, the infection in most cases being in the atory tract, though it might be anywhere in the ; 44 per cent. were attributed to tonsillitis, r cent. to scarlet fever, 20 per cent. to infected ds, 16 per cent. to pyrexia of unknown origin, cent. to otitis media. One authority had placed lar origins as high as 75 per cent. Apical l sepsis was agreed to be an important cause.

ıat determined the incidence of nephritis in infections? It was not the type of organisms rned; the condition could follow all forms of ococci, and occasionally pneumococcal strains found. Nor was it the severity of the infection ıch; mild ambulatory cases of scarlet fever yet lead to severe nephritis. Prof. de Wesselow led cold as an important factor, and it probably ed largely into the causation in trench nephritis, latter was common wherever stationary warfare een established; the Federal Army in the U.S.A. ed greatly from it. In war, too, infection ıncreased by the frequency of septic and ver- ıs wounds. Many cases of acute nephritis were ıbly missed, since in the acute stage it was very ient. After tonsillitis many people might have erular nephritis as a late sequel without knowing He thought the present way of treating litis was irrational. A case of scarlet fever robably detained in bed for three weeks, whereas e of tonsillitis, which probably carried as big of nephritis, was allowed up as soon as the erature came down. He was not advocating a long bed treatment for tonsillitis as for nephritis, xaminations of the urine in the second and third after tonsillitis would prevent the subsequent opment of nephritis in many cases. The ıosis of acute glomerular nephritis in children admittedly better than in adults, possibly ıse the mother quickly called in a doctor, whereas ıdult did not seek medical advice until much The vast majority of cases of acute glomerular ritis cleared up, the urine being free of albumin ır later; 6000 men who had had trench nephritis ed no trace of nephritis when examined for on.

ıere remained the class in which albumin and persisted and became chronic. A few of these a short stormy course, with œdema, hyper- on, and renal inadequacy, and might die in a months. Most of them, however, were relegated latent group, those apparently fit who yet passed They constituted an obscure underworld of nic nephritics. The condition could be said, in neral way, to shorten life, and insurance officers d on that idea. But Addis quoted a case in which erminal uræmia did not supervene until 55 years the original nephritis. The infection of a ey might persist long after the original site of tion—such as an infected finger wound—had red up; he had seen cases in which removal of focal infection aggravated the kidney condition. vas wise to remove the focal infection, but in y cases the nephritic disease was not arrested by means. There was need of evidence as to the t effect of dealing with the focal sepsis.

r. **Bernard Myers** said that in children death ırred within a few years of the onset of the nephritis to even mild scarlet fever, and in his experience tment had been very disappointing. With regard ıdults, in several families whose members began to show evidence of nephritis at about 50 years of age, none lived beyond 60; all apparently had vulnerable kidneys, the cells of which could not continue under the stress of life when the body was declining.

DOUBTFUL VALUE OF STATISTICS.

Dr. **H. Morley Fletcher** felt doubtful of the value of statistics on such a subject as nephritis, even when emanating from the Registrar-General's returns, since so many cases were certified as having died of nephritis when that was not the fatal disease. He pointed out that most of the remarks so far had dealt with infective, not non-infective nephritis. Contrary to what Dr. Myers had said, he had found that acute hæmorrhagic nephritis in children often terminated favourably, and the child might grow up without giving evidence of kidney damage, even on renal efficiency tests. But in adults he had not seen such a case clear up; usually it terminated fatally after a short term. He thought a long-standing *B. coli* infection of the kidney might be a factor in bringing about the chronic diffuse nephritis which was manifest between 17 and 25 years of age. He went on to speak of nephrosis, and the slowly progressive cases of "renal rickets."

Dr. **A. F. Hurst** spoke highly of Dr. Osman's work on the biochemical side, in recognition of which a number of beds and a special out-patient department had been placed at his disposal for dealing with and studying these cases. He thought some of his arguments, based on the statistics, were somewhat fallacious, especially as he added so many deaths from cerebral hæmorrhage, heart disease, and cirrhosis of the liver to his total of deaths from nephritis. One might, in the same way, say that 95 per cent. of cases of cirrhosis had some evidence of tubercle, and so should be added to the deaths from tuberculosis. He did not think it was possible to say that 20 per cent. of patients with cirrhosis died of nephritis, however severe the latter might be, because they also died from their cirrhosis. He stressed the importance of the treatment with alkalis. By prophylactic treatment after acute infections, such as scarlet fever, it was possible greatly to reduce the incidence of nephritis; in scarlet fever the mortality had come down under this treatment from 5 per cent. to under 1 per cent. He agreed that there was a danger after removing septic foci of a flare-up of the nephritic condition, and that was one of the ways in which vaccination was of value; for if an autogenous vaccine were given two or three times before the infective focus was removed the danger of such nephritic exacerbation was very greatly reduced. He regarded the constitutional factor as very important. He spoke of a family in which 25 members died of nephritis in four generations. If relatives in such families had periodic examinations, it was probable that the average life would be considerably prolonged.

EFFECT OF NASOPHARYNGEAL SEPSIS.

Sir **William Willcox** said it would be generally agreed that prognosis and determination of ætiology was more difficult in cases of glomerular nephritis than in any other cases. He confirmed the importance of infections of the respiratory tract. In a large proportion of cases the tonsils seemed to be the starting point, but even if the tonsils were removed other septic foci were likely to be still active and to perpetuate the nephritis. During the war he was struck by the remarkable progress to recovery made by the many trench nephritis cases he saw;

and analogy on analogy. Analogies were very dangerous in medicine, as in other branches of science. The pathological characteristic of cancer was the power of autonomous growth, and this was entirely explicable in terms of things known to be true in other diseases, rendering these analogies unnecessary. The production of a new tumour from a tumour filtrate was quite precise and specific; the filtrate of the Rous sarcoma always produced a spindle cell, and had been doing so for 21 years. Each filtrate reproduced the cell from which it came, two factors being necessary, an intrinsic and an extrinsic. The gene theory had had a greater advantage than any other, but remained largely speculative.

Mr. LOCKHART MUMMERY, in reply, said that the virus theory demanded the assumption that an infective agent could maintain amazing specificity for years on end; no other infective agent known would reproduce itself consistently in this way. Only something producing gene changes could do this, specially in the minute quantities used. What, he inquired, did the cell-free filtrate do in the animal into which it was introduced?

MEDICAL SOCIETY OF LONDON.

Non-infective Nephritis.

AT the meeting held on March 14th, Mr. HERBERT TILLEY, the President, being in the chair, a discussion took place on non-infective nephritis.

NEPHRITIS AS A CAUSE OF DEATH.

Dr. ARTHUR OSMAN, who opened, said the title "non-suppurative nephritis" would have better limited the debate, since most forms of nephritis encountered in practice were infective, either directly or indirectly. He invited a consideration of bilateral non-suppurative inflammation of the kidneys as a whole, disregarding the various types into which kidney disease had been divided. He first drew attention to the wide prevalence of this group of diseases in the community. It ranked seventh in importance as judged by the causes of death as given by the Registrar-General, preceding ones including cancer, rheumatism, heart disease, tuberculosis, and asthma. During the past century and right up to the present time nephritis had been steadily on the increase, except for the years 1915 to 1920, when there was a definite drop, probably connected with the war. It was not merely a question of the withdrawal from the general population of a large number of healthy men for Army purposes, as the same drop was seen in women. As chronic nephritis was a disease chiefly of the elderly, care must be taken that the proportion of elderly people to the general population was taken into account, and in this country the proportion of elderly persons living had greatly increased since 1911. Japan and U.S.A. showed a very high death-rate from this cause; and at the other end of the scale stood Turkey and Belgium, while Scotland showed better figures than did England and Wales. He had found it impossible to correlate these figures with such factors as climate, racial characteristics, and diet, but in considering these comparative figures regard must be had to such tropical diseases as malaria, and to hookworm disease and syphilis in various parts of the world; the relative consumption of alcohol might have significance, though it was difficult to say in what direction. So far, he had spoken of deaths certified as having been due to nephritis, but it would not be disputed that nephritis was present in a large number of people who appeared to owe their death to other diseases. Herringham had found, on investigating 3500 autopsies, that 22 per cent. of the cases from medical wards alone had renal disease; 37 per cent. of those with renal disease died of nephritis. It was significant that 95 per cent. of cases dying of cerebral hæmorrhage had renal fibrosis. He had analysed the histological reports of sections in 2000 autopsies at Guy's Hospital and had found that certainly 95 per cent. had chronic nephritis of a type usually called primary nephritis; there were changes in the capsule or in the glomerular tuft. In 1929, 25,000 deaths occurred in this country from cerebral hæmorrhage, and one could assume that in a large proportion chronic nephritis was a terminal event. Of 131 autopsies on cases of cirrhosis o liver 54 per cent. showed renal disease. Probably a large proportion of cases certified as having died o valvular disease of the heart had chronic nephritis Herringham had found that of 255 patients over 2 years of age who had died from valvular diseas of the heart, 36 per cent. had renal disease. Thes figures were based upon macroscopic inspection but Dr. Osman thought that histological examinatio would probably confirm them. Many elderly pe with functional nephritis who died perhaps afte operation or anæsthesia would not have died ha their kidneys been functioning better. The numb of such cases could not be assessed, but if any mea could be found of arriving at the proportion of peop who died from functional inadequacy of the kidne he thought that nephritis would be found to ran fourth among the important causes of death in th country, the position it occupied in the United Sta of America. He thought he had established t fact that nephritis was one of the chief causes death in this country, and that it was still increasi

THE INCIDENCE OF NEPHRITIS.

Prof. L. D. S. DE WESSELOW spoke of the investi tion into the cause of trench nephritis he had carri out in association with Prof. H. MacLean on a v large scale. Some 50,000 infantrymen were examin these men having just landed in France after co pleting three months of training at home with breaking down or being marked down into a lo category. They were not very fine physical sp mens, but it was at a late stage of the war and th represented the average working population. Morn urines were examined, and after excluding all who were passing pus or had spermatozoa, it was fou that 5 per cent. had albuminuria, 2 per cent. high degree. Epithelial casts were present in per cent. The conclusion was therefore justified t 1 per cent. of presumably fit men were suffering fro definite grade of albuminuria which led to the pass of epithelial casts. Very few of these nephri broke down under the exposure and dampness trench warfare, sufficiently to cause their admiss to hospital. Figures on this point were, howe largely spoiled because at this stage in the war wastage of infantry was about 75 per cent. of strength every three months. He did not think men in question had hypertensive conditions, as t were men under 40, but they had a chronic lat glomerulo-nephritis, and at some time in their li they had probably had nephritis without having kno it. Hæmorrhagic nephritis was the most interest form, and, if hypertensive nephritis was exclud the most common. It presented possibilities

REVIEWS AND NOTICES OF BOOKS

Midwifery.

By Ten Teachers. Fourth edition. Edited by COMYNS BERKELEY, J. S. FAIRBAIRN, and CLIFFORD WHITE. London: Edward Arnold and Co. 1931. Pp. 740. 18s.

THE fourth edition of this well-known work shows changes in the personnel of the contributors, though the schools represented remain the same. Mr. Clifford White has taken the place of Mr. Russell Andrews as a member of the editorial trio. Several of the chapters have been completely rewritten and new matter has been included.

This book was written with the primary object of preparing the candidate for his final examination, but since most doctors after qualifying continue to consult their accustomed text-book, it is necessary to consider the work from the point of view of the practitioner as well as of the student. The volume contains very much that is good and a little that is less good. The teaching throughout is on orthodox lines; sometimes so strictly orthodox that the reader ceases to feel the personality of the writer behind the lines. Controversial issues are for the most part avoided, and there is perhaps some danger that the student, however hungry at the outset, who is fed so consistently on dogma, may have his appetite dulled. There are five sections: (1) the physiology and pathology of normal pregnancy; (2) normal labour and abnormal labour; (3) the puerperium; (4) the new-born child; (5) relief of pain and suffering in obstetric practice.

The first section is clearly written and well illustrated. Toxæmias are accurately described. The wisdom of placing albuminuria of pregnancy in one chapter, and pre-eclampsia and eclampsia in another, is doubtful. In dealing with hyperemesis gravidarum more information might be given as to the indications for terminating pregnancy; the significance of jaundice is not mentioned. On the other hand, the great danger of rapidly emptying the uterus from below, even when the gestation period is less than three months, deserves more emphasis than it gets here. The section on hydatidiform mole is excellent. Reference is made to Aschheim's work (the name is wrongly spelt), but not of the important application of the Zondek-Aschheim test in the diagnosis of chorion epithelioma. Syphilis in pregnancy is but scantily treated, and in order to study this subject one has to read three sections of the book—diseases of pregnancy, diseases of the placenta, and diseases of the new-born. The section on the mechanism of labour follows orthodox lines. In the section on breech deliveries no mention is made of the value of a preliminary episiotomy in a primiparous patient in order to allow of an easy delivery of the after-coming head, and the advice to deal with the arms as soon as the feet slip out may not meet with general approval. Fig. 131 does not depict a "sacroposterior position" as is stated in the legend. The section on contraction of the pelvis is very good, and the details of the management of a case of disproportion are excellent. The legends of Figs. 174 and 175 appear to be reversed. In the section on artificial infant feeding, perhaps undue prominence is given to complicated mixtures containing extra fat, lime water, and barley water. Stress is laid on the addition of extra fat to diluted cow's milk, but there is no warning of the need to reduce the fat intake in certain types of case. The addition of a "teaspoonful of 50 per cent. cod-liver oil" to each 5 oz. of feed seems to be excessive. It is curious that attention is not drawn to the danger of scorbutic symptoms developing in artificially fed infants; the use of fruit juice in supplying the lacking vitamin C is not mentioned. In dealing with white asphyxia of the new-born, the importance of protecting the child from further shock is stated, but the value of this advice is lessened by the accompanying description and pictures of Sylvester's method of artificial respiration which receives priority of place in the methods of resuscitation. The use of lobeline is not mentioned.

The volume ends with a full description of the method of giving a blood transfusion and the means whereby the blood groups may be determined. This is an excellent and valuable section and deals with a subject which is too often omitted by teachers of midwifery. We note with satisfaction that throughout the book the medico-legal aspect of the subject is constantly kept in mind, and much useful advice on these matters is given.

The book well fulfils its prime object of supplying the student with a simple and straightforward account of modern midwifery practice.

Geschlechtskrankheiten.

Second edition. By Dr. ROBERT OTTO STEIN, Professor of Dermatology and Syphilology in the University of Vienna. Munich: J. F. Lehmann. Pp. 219. M.10.

THIS is a second enlarged edition of the work by Prof. Stein which first appeared in 1921. In this country we are accustomed to look upon syphilis, ulcus molle, and gonorrhœa as the venereal trilogy, with pediculosis and scabies closely associated. Dr. Stein leaves out scabies, but includes as venereal diseases: pediculosis, herpes genitalis, molluscum contagiosum, acute ulcer of the vulva due to the *Bacillus crassus*, and lymphogranulomatosis inguinalis. The treatment described of all these conditions follows conventional lines in the main. Syphilis, however, seems to be less radically treated than in this country. Primary syphilis is defined as that stage in which, though spirochæte-positive, the Wassermann is negative when treatment starts. This is "cured" by two courses of neo-salvarsan and bismuth, with a two-month interval between treatments. The test for cure is a Wassermann negative reaction one year later. Any case then positive is treated as a secondary syphilis. Secondary syphilis is defined as any early case with a positive Wassermann. Here the treatment is three courses of neo-salvarsan and bismuth, with two-month intervals between courses. Further continuations are based on the Wassermann. A fixed positive Wassermann which is discovered six to ten years after adequate treatment, when present without clinical signs, is not considered an indication for further treatment; but a positive cerebro-spinal fluid Wassermann is a condition calling imperatively for malarial therapy. Tertiary syphilis is treated with small doses of neo-salvarsan and iodides.

The section on gonorrhœa is much less complete than that on syphilis. In the acute stages reliance is placed on the organic silver preparations, intravenous trypaflavin, and balsams by the mouth. Chronic posterior urethritis is still treated in Vienna he wished one could see the same in ordinary hospital cases of nephritis. A patient with glomerular nephritis left untreated went steadily downhill. He always insisted on a routine X ray examination of nasal and other sinuses in these cases; it was surprising how many revealed sepsis. He spoke of successes he had had by immunising the blood of a healthy person with streptococcus from the suffering person and giving several 20 c.cm. blood transfusions. He advocated steady perseverance in treatment, even in apparently hopeless cases.

Dr. E. P. **Poulton** referred to the value of the urea-concentration test and of the urea-clearance test. In removing diseased teeth, a preliminary clearing of the pockets of pus might ward off an exacerbation of symptoms.

Dr. T. **Jenner Hoskin** said he had long felt that some of the old nephritic patients with hypertension owed their condition to a scarlatinal basis early in life. These people had high blood pressure before the normal time. He appreciated the great value of the alkaline treatment.

Dr. **Bernard Schlesinger** thought the increased incidence of nephritis was to some extent attributable to a wave of streptococcal infection immediately after the termination of the war. If tonsillitis played such an important part in causing nephritis, why did rheumatic children, who showed a high incidence of tonsillitis, seldom have nephritis? In 2000 rheumatic children under his observation there was no sign of nephritis, though their urine was examined every week.

Dr. J. H. **Gibbons** spoke of alcohol and syphilis as contributory factors.

Dr. H. **Gainsborough** alluded to unexpected recovery in cases of nephritis of severe degree. One was a postman who had the disease nine months, and had a systolic pressure of 210, high blood-urea, and renal retinitis, with advanced vascular changes; he recovered and was able to resume his work.

NEW INVENTIONS

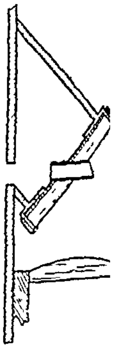
A DEVICE FOR PREVENTING GLARE IN ELECTRIC OPHTHALMOSCOPES.

The introduction of the electric ophthalmoscope has greatly increased facilities for the examination of the interior of the eye, but the internal position of the source of the illumination within the instrument has produced certain new difficulties which the older reflecting ophthalmoscope did not possess. The electric lamp within the stem of the electric ophthalmoscope throws a beam of light parallel to the instrument, and this beam must be bent at right angles to enter the eye of the patient. Prisms and mirrors of various designs have been used to effect this bending. The desideratum is such a complete bending of the rays of light into the eye of the patient that the surgeon has a clear peep-hole through the instrument along the beam of light, and free from all disturbances such as will be caused by rays of light that may be diverted backward from the instrument so as to reach his own eye. If there are such aberrant rays the surgeon cannot see the fundus clearly by reason of the haze that is caused by the rays. The effect is somewhat similar to that disturbance to visibility produced by the rays of the head-lamps of a car when there is a slight mist at night. These disturbing effects have become more evident with the increase in power of the light available.

The aberrant rays are brought about by several conditions. If a glass mirror with a drilled hole be used in the ophthalmoscope the beam of light will impinge upon the upper edge of this hole, and no matter how it may be blackened this edge will scatter a blaze of disturbing light. If the mirror has no drilled hole, but only a gap in the silvering, the hinder surface of the glass itself will reflect any light that may fall upon it from above the ophthalmoscope, and the slightest imperfection in the glass or dust upon it will increase the disturbance.

To overcome this defect, Marple cut out the upper edge of the mirror and used one of U shape. It was very successful, but the mirror was too fragile. A polished stainless steel mirror of U shape was substituted, but this has two drawbacks in that it has a lower reflecting power and soon scratches, still further reducing the amount of light reflected. Prisms, such as were used in the first ophthalmoscopes, avoided some of the difficulties, but if they are well designed they are costly and permit very little variation o the beam, while the inexpensive ones are inefficient

Recently, in discussing electric ophthalmoscope with Mr. J. W. Tudor Thomas, of Cardiff, he told m that there had come into his possession an instrumen the origin of which he did not know, which was fre from these defects. A small tube had been fitte into the drilled hole of the glass mirror. This devic is the simplest, most natural, and effective correctio of the one difficulty of the electric ophthalmoscop It does exactly what we instinctively do to protect our eyes from the glare. We shield them with our hands, or with hat-brims, or we fit vizors to the wind-screens of our cars.



Section throu
mirror fitt
with gla
shield.

A small thin-walled tube is mounted within the hole of the mirror of the ophthalmoscope, *the forward* end of the tube is cut at an angle so that there projects from the hole of the mirror a crescentic ledge or shield. This shield fits the lower edge of the drilled hole and projects just sufficiently to cast a shadow over the hole. When the shield is in position no aberrant rays can be diverted into the surgeon's eye, and he gets a perfectly clear view into the patient's eye. For a mirror set at an angle of 45° to the beam from the lamp, and a hole of 2 mm. diameter, the shield fitted to the lower edge of the hole must project 2·5 mm. to provide complete protection. The shield is made of metal, and is fitted to the metal bed-plate of t mirror, but is independent of the mirror glass, so that it *secure and not likely to be broken.* Also the mirror gl can be detached without disturbing the metal shield.

One small difficulty arose in the use of the devic When the beam from the lamp was exactly centr to the mirror, it was found that the shield cut o the focused rays when they met at the position the shield. This difficulty was overcome by slight decentering the lamp, so that the beam when exact focused upon the mirror impinged upon it to o side of the drilled hole. This decentering has drawback. Messrs. Rayner, of New Bond-stre have fitted this shield to the new electric ophthalm scope made by them for me, and which was describ in your issue of Jan. 23rd, 1932. The device is a re advantage, and it will be the standard pattern. has been fitted to other instruments, and has effect a great improvement in each case.

London, W. N. **Bishop Harman**, F.R.C.S.

BELLE VUE SPA AND HOTEL
TREFRIW, NORTH WALES

The combination of medical treatment and comfortable residence amid beautiful scenery offers great attraction to visitors as well as patients.

Special facilities are provided for those requiring treatment.

Thirty bedrooms, magnificent lounges, billiard room, tennis court, eight and a half miles of salmon and trout fishing, and golf courses within easy reach. The new bath and treatment rooms within the Belle Vue Spa's grounds, recently opened by an eminent surgeon, are equipped with the most up-to-date apparatus for electrical treatment under medical supervision.

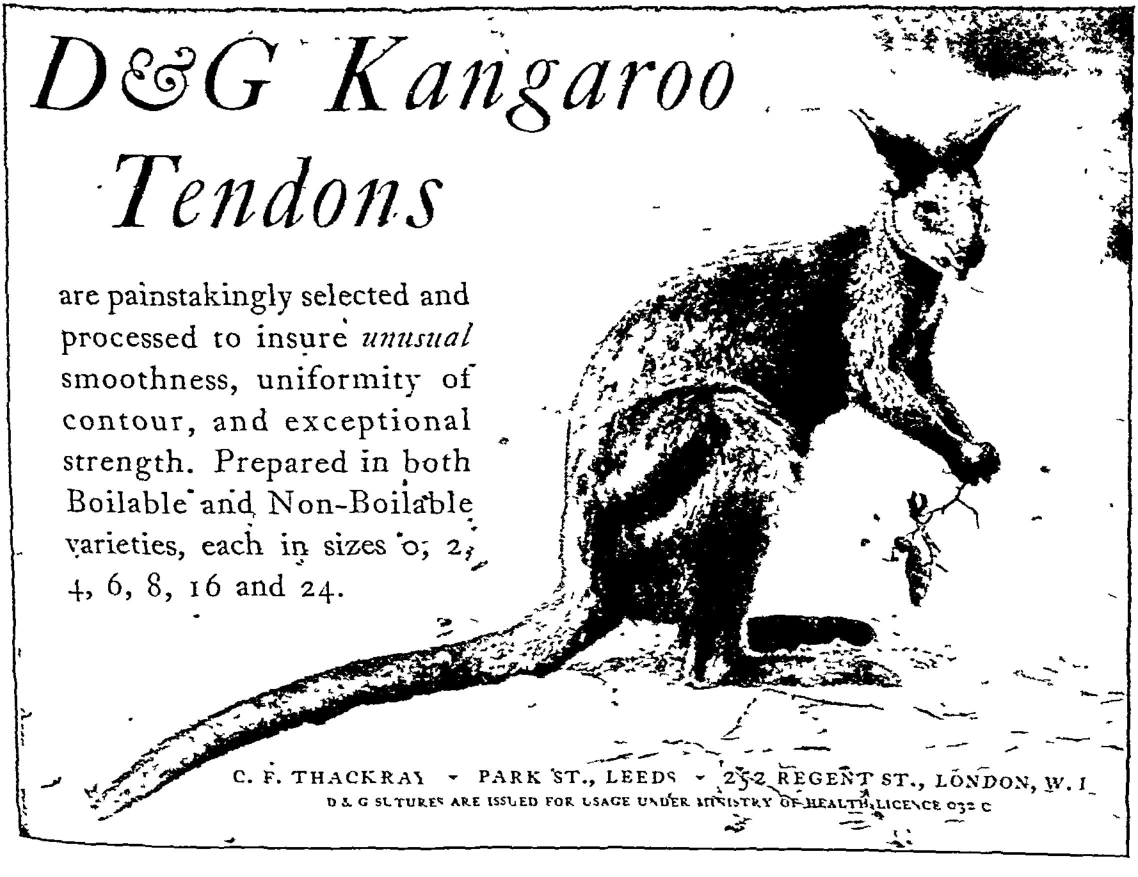
The chalybeate baths for Ladies and Gentlemen are situated on each side of the treatment room.

The Belle Vue Spa sulphur-iron water (ferrous sulphate), described by medical men as the purest and most highly concentrated in the world, is collected from the living rock according to medical advice, so as to prevent any air coming in contact with the iron water.

Sufferers from Rheumatoid Arthritis or Osteo Arthritis, who have been bed-ridden for months or years and want to walk again without pain, can avail themselves of the Hœfftcke Ambulatory Extension Treatment under medical supervision.

This treatment has been favourably commented upon by many eminent medical men in their books and also in the medical papers.

For full particulars apply The Secretary, Belle View Spa, Trefriw, N. Wales.



D&G Kangaroo Tendons

are painstakingly selected and processed to insure *unusual* smoothness, uniformity of contour, and exceptional strength. Prepared in both Boilable and Non-Boilable varieties, each in sizes 0, 2, 4, 6, 8, 16 and 24.

C. F. THACKRAY · PARK ST., LEEDS · 252 REGENT ST., LONDON, W. 1

D & G SUTURES ARE ISSUED FOR USAGE UNDER MINISTRY OF HEALTH LICENCE 032 C

with Guyon's syringe and silver nitrate. The section on gonorrhœa in women is disappointing. None the less this is a most valuable work, mainly on account of the 75 beautifully produced and life-like coloured illustrations. With the exceptions of MacCormac's edition of Jacobi's Dermachromes, and McDonagh's work on Venereal Diseases, there is no text-book in English remotely approaching this in the excellency of its illustrations. It is a marvel of production at the price.

Fields of Psychology.

By Glenn De Vere Higginson, Assistant Professor of Psychology, University of Illinois. London: George Allen and Unwin, Ltd. 1931. Pp. 613. 15*s.*

The title of this book has been wisely chosen because its subject matter illustrates the breadth and comprehensiveness of psychological facts and psychological methods. As the book concerns a study of man in relationship to his environment, the author has found it necessary to deal with heredity and environment and animal behaviour exhibited in reflexes, tropisms, and instincts. This gives a useful background to individual human psychology. The psychology of social formation and such differential phenomena as race, sex, and temperament are then discussed. Interesting chapters are devoted to efficiency, and such everyday subjects as advertising and salemanship are adequately considered. The psychology of crime is dealt with in relationship to insanity, and such legal problems as testimony, responsibility, and punishment are given due attention. The book contains also some useful chapters on the varieties of mental disorder and their treatment by modern methods. It is richly documented, and for this reason is a valuable introduction for all those who wish to delve into specific psychological problems.

Towards National Health.

By J. Anthony Delmege, M.R.C.S., L.R.C.P., D.P.H. London: William Heinemann (Medical Books), Ltd. 1931. Pp. 234. 21*s.*

To those who have occasion, from time to time, to seek accurate information about the public health movements of the past, this book will be very welcome. It traces the development of hygienic ideas and practice from the time of the early civilisation of Crete, Egypt, Palestine, Greece, and Rome, through the dark and middle ages to modern times, until the passage of the Great Public Health Act of 1875. Inevitably the history of public health in this country in the sixteenth, seventeenth, eighteenth, and nineteenth centuries occupies the major portion of the letterpress, and due notice is taken of the relevant [illegible] industrial, political, and religious [illegible] work is comprehensive and accurate. There are many illustrations, most of them interesting and all well reproduced, but their value would have been increased if their origin and exact dates had been given.

Journal of Pathology and Bacteriology.

The March number (Vol. XXXV., No. 2) contains the following papers: The spleen in streptococcal infections, by J. W. Orr (London). Experimentally in rats the earliest change appears in the lymphocytes and histiocytes on the margin between the lymphoid follicles and the pulp: polynuclear leucocytes appear at a later stage.—Completely healed dissecting aneurysm of the aorta with obliteration of the sac, by T. Shennan (Aberdeen). A man of 64 in whom four partial ruptures of the aorta had occurred, the last into the pericardium and fatal. Dissecting aneurysms do not begin in atheromatous ulcers as is commonly supposed.—Some observations on anticomplementary sera, by R. D. Mackenzie and R. S. Marshall (Nigeria). Common enough in natives in Northern Nigeria to interfere with complement-fixation tests.—Natural immunity to streptococcal toxin, by L. M. Bryce and F. M. Burnet (Melbourne). Many infants start life with a supply of staphylococcal antitoxin derived from their mothers; this soon fades away and is replaced by antitoxin made by themselves in response to infection and subinfection. —Some observations on cellular immunity to snake venom, by C. H. Kellaway and F. E. Williams (Melbourne). The hearts of rabbits immunised to cobra venom are more resistant than those of normal animals in perfusion experiments, but the authors think that this is due to residual traces of antibody rather than a change in the cells themselves.—Cellular immunity and antibody in the tissue spaces by F. M. Burnet, C. H. Kellaway, and F. E. William (Melbourne). Experiments on the pulmonary an coronary circulation yielded no evidence of an inherent cellular resistance in actively immunise animals which could not be explained by antibod in the tissue fluids.—The toxicity of irradiate ergosterol, by J. B. Duguid, M. M. Duggan, an J. Gough (Cardiff). An excess of vitamin D produc arterial lesions much more easily in rats on a synthet diet rich in calcium than with normal food; t presence or absence of other vitamins is relative unimportant.—Disease in relation to carcinoge agents among 60,000 experimental mice, by J. Twort and C. C. Twort (Manchester). A valual review of the pathology, other than neoplastic, o great number of mice painted with various carci genic tars and oils, and similar substances. Th do more to the animals than produce tumours; peculiar lipoid degeneration of the liver and extens hyaline change in the liver, adrenal, thyroid, and s are particularly notable. Many parasites described.—Some properties of immune sera act against fowl-tumour viruses, by C. H. Andre (London). Birds bearing either of two slow-grow tumours develop antibodies which neutralise activity of filtrates of the Rous tumour.—Staph coccal toxin and antitoxin, by H. J. Parish W. H. M. Clark (London). Active toxin can prepared by Burnet's method and may be detoxica with formaldehyde. The antitoxin is efficaci against toxin and to some extent against live cultu —Two parathyroid tumours without osteitis fibro one associated with acromegaly, by G. Hadfield H. Rogers (London and Bristol). As might expected, tumours do not always produce the s effect.—Carcinoma of the pituitary gland abdominal metastases, by M. D. Gilmour (Glasg An example of a rare degree of malignancy in a wo of 55.—The relative incidence of the human bovine types of tubercle bacilli in human tubercu in Scotland, by A. S. Griffith and W. T. Mu (Cambridge and Glenlomond). Confirms with m fresh data the previous observations that bo infections are relatively more important in Scot than England. The explanation remains obscur Immunity to Jensen's rat sarcoma produced by tu extracts, by H. Chambers and G. M. MATERNITY HOSPITAL SERVICES.

THE functions of a maternity hospital differ rom those ordinarily fulfilled by a general hospital y the inclusion of attendance on patients in heir own homes and by the much more prominent lace occupied by services of an educational and ocial character. Since the supervision of the xpectant mother came to be recognised as an ntegral part of midwifery practice, wider developnents have taken place in varying degree and long somewhat divergent lines in individual nstitutions and there is great need to facilitate omparison of methods employed and results ttained for the information and common good of all hospitals concerned. The paper by Prof. MUNRO KERR and Dr. MACLENNAN on the factors influencing mortality in maternity hospitals (see p. 633) is a sequel to one published last year[1] on the mortality and morbidity in the domiciliary services of maternity hospitals in which Dr. SHARMAN collaborated with Prof. MUNRO KERR. The two together form a striking picture of the work done by a large maternity hospital. The communication in our present issue describes an attempt to follow the plan adopted in the Interim Report of the Departmental Committee on Maternal Mortality and Morbidity, that of classifying the deaths by a form of inquest, or post-mortem inquiry, under the heading of the particular "primary avoidable factor" thought to have determined the tragedy. Admittedly the determination of such a factor must be largely a matter of personal opinion, but though investigation of all cases by one observer may be impracticable, at least an agreed form of presentation is essential to progress. Many interesting points arise out of the more recent study and these are clearly summarised at the end of the paper. Here we would draw attention particularly to the discussion of the institutional problem, where the various factors affecting the results obtained by an institution are considered. The authors complain of the difficulty confronting those who attempt to compare the results attained by the different institutions because of failure to record them in accordance with the unified system proposed by the Obstetrical Section of the Royal Society of Medicine some years ago, after consultation with the larger maternity hospitals throughout the country. This first step in the right direction was a very useful piece of work. To be effective, however, the plan outlined must be adopted by all concerned and it is to be hoped that the few remaining hospitals that continue to issue reports of the old individualistic type will soon appreciate the advantages of a uniform pattern in the presentation of material facts.

One conclusion reached by Prof. MUNRO KERR and his collaborator is that "hospitals with a unified control, or, better still, with a resident master, show the most satisfactory results." From the point of view of teaching, whether of undergraduates or post-graduates, the superiority of what may be termed from its outstanding example, the "Rotunda" system is generally admitted. This system was the one advocated by the Obstetrical Section in a memorandum issued in 1919 on the training of medical students. It gives opportunities for continuous teaching on obstetric complications that cannot be obtained under the system of a visiting staff and enables the student to see the conduct of a case throughout its stages by a senior and experienced officer. The new evidence that it is also advantageous in the care of patients strengthens the plea for its wider adoption. Two factors apart from the organisation of the institution are thought to have an important influence in producing differences in mortality- and morbidity-rates—the nature of the population served and the type of case admitted. The fallacy arising from the latter may be minimised by recording separately the "booked" and the "unbooked" or emergency cases. The further division, as in the Glasgow figures, into emergencies sent in by doctors or midwives and those women who do not apply till the end of pregnancy or the onset of labour—many of them in order to escape a supervision they dislike—adds no difficulties, for the two together are the same as the single list of unbooked cases. It should however be remembered that the maternity hospital in Glasgow refuses no women because they have not booked and that, while the antenatal supervision of many of the booked cases was inadequate, presumably it is owing to the women not attending the clinics at all or not often enough. The efficiency of the antenatal supervision depends on other factors than the nature of the population served, such as the power of the institution to acquire the confidence of the women and thus to secure their regular attendance; visiting by nurses, lady almoners or health visitors, together with a proper system of recording which of the patients have been told to report again, will greatly lessen the number of those who fail to obey instructions. When the supervision of the "booked" cases seems inadequate, attention should be directed towards establishing closer contact with the mothers.

A test of efficiency in another direction is the degree of success attained in avoiding the transference of patients attended at home into hospital as emergencies; to this end arrangements should be made for the confinement within the hospital of women whose labour seems likely to be complicated. These aspects of maternity work were

Metatone

A Palatable Vitamin B Reconstructive Tonic

HARDLY a day of a physician's life is passed without one, or more, of his patients requiring a tonic. Metatone is a general tonic particularly suitable for such occasions. In the treatment of general debility, during convalescence, in neurasthenia, anæmia and rickets, after surgical operations and during pregnancy and the period of lactation, Metatone may confidently be prescribed for its reconstructive, restorative and tonic properties.

Metatone is an agreeable fluid combination of vitamin B, nucleinic acid and glycerophosphates, containing in each fluid ounce:—

Vitamin B Extract	10 grains
Nucleinic Acid	2 grains
Calcium Glycerophosphate	4 grains
Potassium Glycerophosphate ...	4 grains
Manganese Glycerophosphate ...	1/2 grain
Sodium Glycerophosphate	2 grains
Strychnine Glycerophosphate ...	1/25 grain

The adult dose of Metatone is one to two teaspoonfuls, three or four times daily, usually after meals.

Supplied in bottles of 8, 16 and 80 fluid ounces.

B

SHOULD ABORTION BE LEGALISED?

LATELY, from the Bench, Mr. Justice McCARDIE emanded an extension of knowledge of contraeption, compulsory eugenic sterilisation, and the galisation of abortion on other than therapeutic rounds. These three measures taken together can e looked upon as practical expressions of a onsistent philosophy of life which is to-day ometimes described as scientific humanism. This ttitude is difficult to epitomise in a sentence. n one of its aspects it implies a disbelief in an ltimate and unchangeable moral law superaturally revealed to man and characterising, as lo physical laws, the essential nature of the niverse. The scientific humanist takes his stand n the changing nature of man. As human needs hange, so also must change the dogmas and moral recepts which regulate social conduct. Since he is he possessor of an intelligence greatly superior o that of any other animal, man is not only entitled but, in this view, bound to make use of his endowment in whatever way he thinks best to secure the maximum happiness and physical well-being of his contemporaries and descendants. In general it may be said that the attitude of the medical profession towards contemporary morality is humanistic rather than dogmatic. In the past, for instance, it was believed that the acquisition of a venereal disease was a heaven-sent castigation for sin. As soon as adequate means of treating venereal diseases were discovered, the question arose as to whether this point of view was compatible with the most efficient prevention and cure of these diseases. The profession had little difficulty in concluding that it was not. In the sphere of psychological medicine, likewise, it has been found that an attitude of strict ethical neutrality on the part of the physician is best calculated to induce the patient to speak of himself without dissimulation and shame, and therefore to lead to the best therapeutic results.

The many problems arising from the rapid increase of population that has occurred in all civilised countries in the last hundred years, and the recognition that much human misery can be prevented by an intelligent regulation of genetic processes, have probably been the two factors chiefly responsible for the publicity which has been accorded to Mr. Justice McCARDIE's remarks. Of the measures he advocated, the provision of medical supervision and instruction in birth control is now rapidly taking place, and the proposal to legalise eugenic sterilisation is receiving increasing consideration from medical men. The last and most drastic proposal—to legalise the practice of abortion—naturally excited the most violent opposition and would now seem furthest from practical fulfilment. The proposal to legalise abortion has hitherto received much less serious attention in this country than in such countries as Germany and Russia, where advocacy of this measure has, since the war, been closely linked with what may be called the birth control movement. For this reason, the appearance of a responsible book upon the subject, written primarily for the medical profession, is to be welcomed. The writer[1] holds that the increasing traffic in abortifacient proprietary preparations—most of them inefficacious—and the state of the law which permits of their indirect advertisement are strongly to be deprecated. With regard to the expediency of combining, as the Russians have done, the legal suppression of both traffic and advertisements with the provision of medical facilities for obtaining abortion, Dr. PARRY expresses himself somewhat ambiguously, but at a meeting of the Medico-Legal Society on March 15th he made it quite clear that he thought it would be deplorable for this country to follow the Russian example. In the discussion which followed, legal opinion was universally in favour of a modification of the law in this country or even of legalisation of abortion, while with few exceptions the medical members present supported the existing position. Mr. CLAUDE MULLINS feared that, in view of the widespread practice of secret abortion, public opinion might so far outstrip the law that juries would acquit prisoners in the face of the evidence, as once they used to acquit prisoners in danger of hanging for theft. The danger to the mother of abortion, even when procured under the most favourable conditions, was fully discussed, but no exact statistics were quoted to show how great this danger was. Dr. W. G. EARENZEY, K.C., pointed out that if secret abortion was as widespread as Dr. PARRY had led the meeting to believe the danger to life of the operation, even in unskilled hands, must have been exaggerated. If it were to be done at all it was better that it should be performed by skilled operators in the open. Lord RIDDELL, who took the chair, thought that women were little influenced by warnings of danger or disablement, and that the demand for the performance of abortion was increasing. The claims of the child were well supported by Dr. LETITIA FAIRFIELD: she mentioned a striking case of a woman raped on a lonely road, who might surely have been justified in attempting to procure abortion; to the profit of history she preferred to give birth to WILLIAM THE CONQUEROR. Such instances, however, are hardly relevant to the situation which has to be faced in modern England. Dr. EARENZEY took account only of the fatal cases reported as following attempts at abortion. Medical men know well that many of these escape detection; as we point out on p. 638, far more harm is done to health than is ever revealed in a court of law. The extent to which this harm is due to the disorderly haste inseparable from the secrecy in which illegal operations must be performed should be explored. "Uniformly satisfactory" statistics are said to have accumulated during ten years' experience of legalised abortion in modern Russia.[2] If these are confirmed after searching investigation they will, from the strictly medical point of view, deserve serious consideration by those planning new legislation appropriate to the outlook and habits of our times.

clearly emphasised in the earlier paper on domiciliary services where attention was drawn to the need for concentrating on an improvement in the attendance of prospective mothers. There also was shown a substantial decrease in the percentage of abnormalities in the district practice in the latter part of the period studied, due apparently to the fact that grave operations in the homes of the patients were discouraged, all cases in which abnormality was anticipated being treated in hospital. Of the 20,000 cases analysed about a fifth were attended by students and the other four-fifths by pupil-midwives, gloves being used by the former but not by the latter. A decidedly lower mortality- and morbidity-rate was shown in the cases attended by students. In this connexion a recent paper by Miss Carter[2] who till recently was the supervising sister of the out-patient district of University College Hospital, London, is of particular interest. It dealt with the effect of better arrangements made for the nursing of the patients in their homes and contrasted the results attained with those of a preceding period before these arrangements were in force. In the earlier period the student went to the case with only a handywoman to assist him, but from April, 1930, he had with him a registered nurse-midwife who subsequently carried out the nursing of both mother and baby. Both carried masks, sterilised gowns, towels, dressings, kidney dishes and dry gloves. The antenatal care was thorough, under 5 per cent. of the patients escaping one examination at least and over 84 per cent. having more than one examination. There were no deaths on the district or among cases transferred to hospital, and the morbidity-rate was taken as the criterion. It showed that the incidence of notifiable pyrexia was reduced to less than half, from 5·2 before to 2·19 per cent. after the advent of the nurses. A strong plea is made for this conjunction of skilled nurses with the students working on the district not only for the comfort and other advantages it brings to the mother, but also for the value to the student in teaching him how to work with nurses, and how much good nursing means to the mother.

All these communications provide welcome evidence of the progressive efforts made by our great maternity hospitals to improve both their care of the woman during childbearing, and the training of medical students and pupil-midwives for the service of the whole community. More might be done to make a knowledge of the results in the institutions and the methods by which they are attained readily available, and as comparable as the variable factors in each permit, if they were set out in a common form. But the chief lesson to be drawn is that the maternity hospital of to-day must provide social as well as medical services, particularly for its out-patients, and must study the special circumstances of the individual mother if it is to do the best for her and get the best out of her.

VACCINE TREATMENT OF DISSEMINATED SCLEROSIS.

In our present issue Sir James Purves-Stewart and Dr. F. D. M. Hocking report the results of the treatment of a further series of patients suffering from disseminated sclerosis with a vaccine composed of the "Spherula insularis." This body was originally described by Miss K. Chevassut in cultures made from the cerebro-spinal fluid of patients with disseminated sclerosis. It is now admitted, however, that similar spherules are found in other circumstances, and the authors report that they have been observed in cultures made from the fluid in a wide range of organi nervous diseases. The spherula has thus shed it insularity and cannot be regarded as specific t disseminated sclerosis. Many successful remedie have been first adopted for theoretical reason which have ultimately proved to be unsound The authors claim that, although the reason which led them to adopt the vaccine treatment c disseminated sclerosis have been shown to b invalid, nevertheless the treatment remains efficacious, and they report both serological an clinical improvement in a proportion of patient thus treated during the period of six month from March to September, 1931. The change which are described in the cerebro-spinal fluid a similar to those reported by Sir James in h previous communication.[1] At that time w expressed the view that "the significance of the changes could have been better appreciated controls had been investigated." This criticis remains valid, for in the absence of controls w are unable to say that the fluid in untreated cas would not have shown equal or even great changes for the better.

The clinical results described by Sir Jam Purves-Stewart do not in our opinion justi any conclusions as to the value of the vacci treatment. It will be widely felt that six mont is far too short a period upon which to base concl sions as to the results of treatment in so chron a disease as disseminated sclerosis. Althoug Sir James reports the after-histories of the fo patients described in detail in his previo communication, he says nothing about the sevent patients who were at that time reported as bei under treatment and who have therefore no been under observation for more than two year No experienced clinician, "bearing in mind th well-known tendency of this disease to underg spontaneous remissions," will feel that the vacci treatment can be credited with the clinical improv ment reported in this new series of cases. Eve however, if it could be demonstrated by observatio over a number of years of treated cases and c controls that the vaccine treatment was beneficia it would still remain to be proved whether th results obtained were better than those achieve by other non-specific therapeutic measures, fo example, those which rely frankly upon th production of protein shock.

tuberculin-tested herds should be adequately pasteurised or, if this is impossible, sterilised or boiled. It expresses a strong opinion that no such processes ought to be accepted as a substitute for cleanliness in production, though it regards pasteurisation, as defined in the regulations of the Ministry of Health, as an effective method of destroying pathogenic micro-organisms. It advises that no milk that has been heat-treated in any way shall be lawfully sold as raw milk, but that it should have some officially approved designation. The committee's findings show that the question of whether pasteurisation impairs the food value of milk has not been conclusively answered, and that considerable evidence exists that pasteurisation reduces the incidence of all milk-borne diseases; it suggests that the sale of milk from free herds as raw or pasteurised be permitted, provided that each kind is officially labelled. Finally, it adopts the suggestion—originally put forward by Dr. Savage—that the larger local authorities should have power: to require all milk sold within their jurisdiction, other than that from non-reacting herds, to be effectively pasteurised; to forbid the importation of milk heat-treated other than by pasteurisation; to enforce compulsory classification of all grades of milk sold within their areas; and to exercise adequate supervision and control over the health of all persons engaged in the industry.

We have given a brief and in some respects an inadequate summary of the findings of the committee. It is for the public conscience to say to what extent its labours are to bear fruit.

THE GERSON DIET.

THE Gerson-Hermannsdorfer-Sauerbruch diet has been tested in Norway in two different institutions with results that are, perhaps, the more impressive because they are published at a stage when critics have had time to collect failures and disappointments wherewith to produce the negative phase in the history of the "cure." At a recent meeting of the Medical Society of Oslo, a paper[1] was read on the use of this diet in tuberculosis of the skin by Prof. E. Bruusgaard, in charge of the Dermatological Department of the Rikshospital, and by Dr. E. Hval. During the past two years all the cases of tuberculosis of the skin admitted to this hospital have been given the Gerson diet with some modifications to suit Norwegian conditions. Great care was taken that the supply of raw fruit and vegetables, as well as of fresh juices, should be liberal, and the average of 2600 calories was made up as follows: protein 77 g., fat 152 g., and carbohydrate 215 g. Of the 75 cases of tuberculosis of the skin thus treated, 62 were cases of lupus vulgaris. Seventeen patients, whose treatment was limited to this diet, were rendered symptom-free—a term which conveys a warning of a possible relapse. There were 29 who were considerably improved and were still under treatment. In some cases a few lupus nodules persisted at the completion of this treatment which was then supplemented by exposures to the Finsen lamp. Among the 24 patients thus treated, 19 were rendered symptom-free, and five were considerably improved. "One may conjecture that diet combined with Finsen light will in the future be the chief treatment in skin tuberculosis." This considered opinion is the weightier for being voiced by an authority noted in the Scandinavian countries for his caution and critical sense. During the dietetic treatment, a marked improvement in the patients' general health was observed simultaneously with the changes for the better in the local condition. It would, indeed, seem that the diet has a general stimulating effect on the natural defences of the body, rather than any specific influence. The tissue-absorbing action of the diet is one of its conspicuous features. Masses of hypertrophic scar tissue, in which lupus infiltrations are embedded, are absorbed with remarkable rapidity. In this way otherwise intractable cases are rendered amenable to Finsen light treatment.

The Gerson diet for the typical clientèle seeking hydropathic establishments has recently been given a trial by Dr. E. Möinichen and Dr. H. Fröshaug,[2] of the Midtstuen hydropathic establishment near Oslo. Among their 45 patients thus treated were 23 suffering from hyperpiesis. "With a background of 25 years' experience with the physical and dietetic treatment of these conditions, some importance may be attached to our impression at Midtstuen that the Gerson diet is considerably more useful than other systems of treatment previously employed."

THE INSURANCE OF PEDESTRIANS.

THE heavy casualties caused by road traffic are regarded by the public with strange equanimity. The total is said to be nearly 200,000 a year, whereof roughly 1 in every 25 is fatal. Arguing that about one-half of the total happen to pedestrians or pedal cyclists, the Pedestrians' Association proposes an amendment of the law. If a pedestrian is knocked down by a motor-car, he clearly cannot recover damages if he himself was negligent; he clearly ought to recover them if the driver was negligent; but what is to happen if neither side was to blame or—a commoner case—if there is no evidence to show who was to blame? What ought not to happen, argues the Association, is that the pedestrian should suffer the whole of the loss; the driver should be made prima facie liable and in fact should pay the pedestrian irrespective of any evidence of negligence. Let Parliament pass a Bill to that effect; the cost to the motorist will only be a slight increase in his insurance premium. Most medical practitioners are motorists. They, like other motorists, will probably answer that it is wrong to remove one hardship by creating another; that Parliament sanctions the present conditions of road traffic and the motorist should not be penalised for taking advantage of that sanction; in fact that motor-cars are not man-eating tigers. To this the Association will reply that in many cases the law already imposes liability to compensate irrespective of negligence. Thus innkeepers are liable for the goods of their guests; common carriers are responsible for the goods entrusted to them; employers must compensate workmen for accidents happening in the course of their employment; railway companies must pay for damage to crops caused by sparks from engines; aeroplanes must make good damage or loss which they cause in their flight, taking off or landing; and so on. Moreover, it was long ago held to be a common law nuisance to bring upon a road a machine which is likely to frighten horses "of ordinary nerve and courage." But this last instance suggests the rejoinder that the average horse has given up shying at motor-cars and that human beings need not despair of adapting themselves to the presence and movements of machines. The statistics of road accidents seem to indicate that the young of the human species have

ANNOTATIONS

THE PROBLEM OF SAFE MILK.

ABOUT a year ago we summed up in a leading article[1] the current evidence on the milk problem, from which it appeared that the milk consumption of this country is considerably less per head of population than that of many others, the defect being ascribed in some part at least to the failure of all concerned to produce an adequate supply of safe milk. The problem centres around the elimination from milk of the bacilli of bovine tuberculosis, although other milk-borne diseases and dirt may act as deterrents. Mention was made of the action of the People's League of Health in appointing a committee to study the whole question of bovine tuberculosis and of the wisdom of suspending judgment until this committee had had time to report. That report, which is now in print,[2] deserves the closest study. The committee itself comprised approximately 100 of the most eminent authorities in the country on every side of the question—medical, veterinary, laboratory, agricultural, and industrial—and it appointed three subcommittees to investigate the incidence of bovine tuberculosis and the most effective means of preventing its spread among cattle and man. The late Mr. E. B. Turner was its first chairman, then Dr. W. G. Savage. It is sufficient to say that no more representative or competent body could possibly be collected in this country to discuss this matter.

On the facts as they exist at present the findings of the committee do not disclose anything very novel. The figures of incidence are scarce, a fact which does not do credit to the Government departments concerned. In the words of the report :—

> Since no comprehensive body of statistics exists in Great Britain other than that in Dr. Savage's books, and since no extensive testing over the whole country or even over a whole county has ever been made, calculations have to be based on samples, the majority of which have not been taken at random.

There is no system by which the results of tuberculin testing or of abattoir statistics are collated. One reason for this deficiency is, conceivably, that the returns of tuberculin tests are confidential, but the committee was evidently considerably handicapped by the absence of this information. The Ministry of Health provided figures for a limited period, and other figures were provided by various investigators, and some were taken from the returns of foreign countries for comparison. The average of the figures available shows that at least 40 per cent. of the cows in this country are infected, though only a minority are infective ; that about 0·2 per cent. of all cows are suffering from tuberculosis of the udder, and are therefore probably excreting living tubercle bacilli in the milk ; that about 40 per cent. of cows slaughtered in public slaughter-houses show naked-eye lesions of tuberculosis ; and that an average of 6·7 per cent. of raw market milk contains living tubercle bacilli. The figures for the incidence in man suggest that about 6 per cent. of all deaths from tuberculosis are caused by the bovine type of bacillus ; that about 2000 deaths occur annually from this cause, mostly in children, apart from an immense amount of invalidity ; and that at least 4000 cases of bovine infection develop each year. The disease has certainly diminished in the past 80 years, and the factors judged by the committee to be responsible for this decrease are improvement in milk production and in child welfare, the fall being accelerated during recent years by pasteurisation and sterilisation.

The part of the committee's work that demands the closest and most urgent attention is, however, its advice on the means which should be adopted to stamp out the disease ultimately, and to check its incidence and its spread while the fundamental measures are being developed, a process which must take a long time. "The obvious aim of all arrangements," says the report, "is the provision of a milk-supply untainted by the bacillus of tubercle." The Milk and Dairies Act, 1915, makes it an offence to sell milk from infected cows, but in order to convict it is necessary to prove knowledge on the part of the defendant, and the provision is therefore only of limited value. The report stresses the necessity for a clear distinction between two problems : (*a*) the eradication of tuberculosis in cattle, and (*b*) the provision of a safe milk-supply ; the first problem is entirely veterinary and should be dealt with by the Ministry of Agriculture, whereas the second problem is essentially medical and should be dealt with by the Ministry of Health. Nevertheless, since the two problems overlap, it is desirable that the two Ministries should work in close cooperation on a joint plan. The measures recommended for the eradication of tuberculosis in cattle are three : (1) to increase the number of tubercle-free herds ; (2) to detect and eliminate "open" cases ; and (3) to encourage the perfection of prophylactic vaccination. The committee urges the necessity for official assistance in the building up of tuberculin-tested herds and suggests several practical measures. It consider that the Tuberculosis Order of 1925 has not led t any appreciable progress towards the eradication o open cases, and anticipates that no real progress ca be expected until a scheme is devised which wi include the herd owner, the local authority, th veterinary inspector, and the bacteriologist. I suggests a number of points with which such a schem should deal specifically. It holds that, in order t secure the goodwill of the farmer, an educationa campaign will be necessary ; in such work th veterinary inspectors could give valuable assistanc As it points out, the extension proposed is along lin already in force. It recommends that the variou prophylactic vaccines available be investigated muc more carefully than they have been hitherto, an that experiments both in the laboratory and on th farm should be actively encouraged. Among measur to provide a safe milk-supply, the committee rul out as obviously impracticable the wholesale slaught of reacting cows, but regards as helpful a routin inspection of all dairy cattle by competent veterinar surgeons, if sufficient funds are available. To increas the supply from free herds, it recommends a mod fication of the Milk Order of 1923 to provide th new names should be given to the different grad of designated milks in order to indicate definitel the nature and quality of each ; that the fee charge for a licence should be abolished ; and that th number of licencing authorities should be reduce These measures, however, belong to the fundament campaign to free all dairy herds from tuberculosi As practical immediate measures the committe advocates that all raw milk that does not come fro abdominal affections already referred to is certain, and the observations of J. B. Carnett, set forth in a number of contributions,[1] are illuminating and suggestive. In effect, he believes that a neuritis of the nerve trunks supplying the abdominal wall is a quite common complaint, a neuritis which may be, but is not necessarily, due to some infective focus in the abdomen, possibly the gall-bladder. More than four years ago he discussed[2] the mimicry of gall-bladder disease in cases of neuritis of the ninth and tenth right intercostal nerves. He mentioned the identical pain at the costal margin rediscovered by Dr. Carmalt-Jones, and sometimes a hyperæsthesia. There are, perhaps, other tender points, where the nerves perforate the rectus sheath or where the lateral cutaneous branches emerge. He insists that the tenderness is as pronounced when the abdominal muscles are thrown into contraction as when they are relaxed, and avers that the spontaneous pain may vary from a dragging sensation to a disturbance which cannot be distinguished from a colic. It is therefore interesting to read that Dr. Carmalt-Jones has found cases of "apparently typical biliary colic, with a tender cartilage," in which at operation "a normal gall-bladder was found." Whether Carnett's views will be established must depend upon the observation of other clinicians. He is careful to point out that the discovery of such parietal neuritis does not exclude gall-bladder disease, and indeed is found often to accompany it; but when other reliable signs, particularly jaundice, the presence of a palpably distended gall-bladder, or a positive dye test are wanting, it does not seem justifiable to proceed to operation.

GOOD AND BAD PROPAGANDA.

THE new British Health Resorts Association has a useful part to play in the near future, and we hope and believe that it will prove equal to its task. But there is undoubted danger in the circumstances of its foundation. At the Hastings conference reported in our columns last week, Lieut.-Colonel R. H. Elliot rightly insisted that the movement would lose the present support of the medical profession if it showed signs of commercialism; but he might have gone further and disclaimed medical interest in any appeal to narrow patriotism. As a profession our object is to treat our patients as well as possible—not only to treat them with British remedies. It would be a great pity if supporters of this Association were to spoil their case by ignoring or dismissing the virtues of foreign travel and foreign cures. No amount of proclamation to the contrary will prevent our remembering that complete change of language, scene, people, food, and climate is often as useful as it is recreative. But this does not mean that the Association has no object. Far from it. Supposing a Londoner felt that Hyde Park might be made more beautiful and that more people might be drawn to enjoy it. Would he begin by saying that the Park had all the charms of the country—birds, lakes, trees, and all complete? If he was wise, he would surely accept the inherent limitations of Hyde Park and say that it was our duty to make it as beautiful as possible, since many Londoners could never go further. It so happens that Hyde Park has in fact become very charming in its peculiar way, so that it is worth while for visitors from the country to come to see it. This, however, is not so much the result of propaganda as of planting bulbs and introducing foreign birds, and employing artists. The amenities of the countryside—that is to say of foreign parts—are again available to rich people now that the ban on money exchange has been withdrawn. At all times and in any case the rich will look after themselves. But the vast mass of our population can never go abroad for health, and it is in the interests of this majority, which at present goes lacking what it could easily have, that we would like the British Health Resorts Association to work. There is much to be done on our coasts, much to be gained from them, and much to be learnt about them. The sense of these aims and objects is in no way dependent on a fashion in economic philosophy.

DUST IN THE COTTON INDUSTRY.

IN 1927 a departmental committee was appointed to inquire into the respiratory disease found among cotton operatives working in card-rooms. The committee worked under the chairmanship of Mr. J. Jackson, Deputy Chief Inspector of Factories, and had as secretary Dr. S. A. Henry. The medical profession was also represented by Prof. George Murray. In the report now published[1] some valuable information about the conditions of the workers is to be found. In the historical review it is pointed out that THE LANCET published one of the first papers to draw attention to the injurious effects of dust in this industry.[2] Various suggestions have since been made as to the exact constituent of the dust which is responsible for damage to health and this problem is still unsolved. The constituents in the dust liberated during the processes of stripping and carding are fragments of cotton hairs and of leaf and seed coat, fungus mycelium, spores, bacteria, and mineral matter; the greatest amount of dust is found in Egyptian cotton. The committee find that much of the dust is due to lack of adequate cleaning of the cotton in the preliminary blowing-room process, and yet more to the practices of "wafting" and "brushing down" to remove dust which has settled on the machinery. A pharmacological test showed that histamine or some allied product was present in aqueous extracts of the finer portions of card-room dust, and this is considered to be capable of causing ill-health, but an allergen may also be present.

The clinical investigation of operatives showed no specific conditions but merely an ordinary bronchitis such as that which occurs in the general population. The committee found that the reduction of dust and improvement in ventilation already carried out had certainly reduced the amount of discomfort and ill-health, but that the sickness-rate from respiratory disease is still higher among male card-room operatives than among other male cotton operatives. There was no marked incidence of tuberculous disease, of silicosis, or of aspergillosis. The committee are of the unanimous opinion that the present excess of sickness among card-room operatives could be considerably reduced, if not eliminated, were the cotton more thoroughly cleaned in the earlier stages—either in the blowing-room or in the process of ginning before import. They consider that an abnormal sickness-rate among workers in a card-room should be regarded as prima facie evidence that dust is not being sufficiently removed and/or that the ventilation is inadequate.

[2] THE LANCET, 1863, ii., 648.

learnt to do so more quickly than their elders. One statement in the Pedestrians' Association's case is challenging. "As the law stands, even a person killed on a pavement has no claim if the driver is exonerated from blame." It is true that in one instance. not long ago, where a motor-car mounted a pavement owing to a skid on a half-frozen road, the injured person's claim failed; the incident was held to be a mere accident and not negligence. But in another case the Court of Appeal decided that the mere fact that a motor-car was found damaging pedestrians on a pavement was at any rate some evidence of negligence. Is it not reasonable to retain some distinction between the motorist who is, and the motorist who is not, negligent?

EAR DISEASE IN FEVER HOSPITALS.

THE problems of prevention and treatment of ear disease in fever hospitals differ from those in ordinary practice, and the clinical conditions and the methods of treatment adopted are not necessarily applicable elsewhere. That part of the annual report of the London County Council for 1930[1] is allocated to Mr. T. B. Layton's account of the treatment of ear disease in the fever hospitals under the Council's control; this makes interesting reading for otologists. When he was first appointed otologist to the fever hospitals ten years ago, his conception of ear disease was that the inflammation spread from the throat to the middle ear, stayed there awhile. and then passed over to the mastoid region. He now believes that the inflammation involves the mucous membrane of the entire middle-ear cleft practically simultaneously in the majority of cases, and that it often subsides with or without rupture of the drumhead. This later view is in conformity with what we believe to be the opinion of most otologists. Early paracentesis of the membrana tympani is generally considered to be of immense value in cutting short the disease; but in Mr. Layton's work, chiefly among little children suffering from scarlet fever, he has found small help from this operation. The principal reason for this failure is the inability to get the patients at the right time, for in scarlatinal otitis pain is rare and, when it occurs, only precedes rupture by an hour or so, rise of temperature is an unreliable guide, and the first symptom of ear disease is a discharge on to the pillow. Routine daily examination of all drumheads was proved impracticable; it took Mr. Layton three hours to examine both ears of 60 patients, and such an examination every day is obviously impossible; but with this early rupture of the drum paracentesis is hardly necessary, though this need by no means diminish the conception of its value in other forms of otitis. In conformity with most of his colleagues, Mr. Layton believes that the cause of chronicity is secondary infection from the meatus; he is further of opinion that the growth of the organisms present in the skin of the meatus can be repressed by keeping the skin dry. He has therefore discontinued syringing and the use of peroxide of hydrogen in the routine treatment of discharging ears, and employs only spirit or glycerin as the basis of applications. But he relies almost entirely on frequent mopping out of the meatus with cotton-wool mops, and teaches quite young children to carry out the procedure for themselves. This is doubtless a very successful method of treatment, but it could be criticised on the grounds that it is impossible to keep the meatus dry when the ear is discharging freely, and that secondary infection may be introduced from the children's hands on to the mops as well as from the meatal skin. In the treatment of mastoiditis with retro-aural swelling, occurring in the acute stage of the fever, he employs Wilde's incision, operating later on the mastoid, however, if the middle ear does not get well. All cases in which otorrhœa persists for more than 21 days are entered in a special report; a number of these are placed in the category of "symptomless mastoiditis," because they have no tenderness or any symptoms except discharge. Mr. Layton does not approve of removing adenoids or tonsils in these cases; he admits that in a small number of cases removal of the lateral portion of the nasopharyngeal lymphoid tissue has had a good effect, but says that there have been as many failures as successes. In our view this small operation would be justified if it succeeds in even 50 per cent. of cases. His objections to a more complete operation are that it removes lymphoid tissue which the patient needs, and that it results in compensatory hypertrophy of such lymphoid tissue as is left. The more usual view is that there is excessive hypertrophy of the lymphoid tissue in such patients, and the general experience is that its removal is frequently followed by cessation of the otorrhœa; the excellent effect on the ear of this operation is also seen in the improvement of hearing which it produces in cases of catarrhal deafness. It is true that hypertrophy of the lymphoid tissue in the pharynx sometimes follows extirpation of tonsils and adenoids, but this is not by any means the rule and does not occur until after the ear has healed. Mr. Layton acknowledges that his views on this matter are quite contrary to those that may be deduced from certain statistics that have been published, but holds them none the less firmly.

THE DIAGNOSIS OF CHOLECYSTITIS.

ELSEWHERE in this issue Prof. D. W. Carmalt-Jones calls attention to a physical sign which he regards as significant of disturbance of gall-bladder function. It is tenderness on palpating the lower border of the right costal margin in the region of the eighth costal cartilage. This tenderness has been fairly constantly present in patients coming under his care, though an analysis of 20 of his cases presented in his paper certainly arouses a suspicion as to the validity of the interpretation he places upon this sign. For though in only two of the 20 cases was such tenderness absent, it was found in five patients who had previously been operated upon for cholecystitis. Presumably some at least of these five people had lost their gall-bladders. Viewed from this aspect, Dr. Carmalt-Jones's contribution invites reflection on that group of patients who suffer from abdominal pain, often in attacks, which simulate very closely those associated with definite visceral disease, and in whom a laparotomy fails to reveal the expected cause, or indeed any demonstrable lesion. It arouses speculation about the true cause of referred pain in abdominal disease. Is there such a phenomenon as a viscero-cutaneous reflex of pain, as Head and Mackenzie believed, or is there only a peritoneo-cutaneous spread which can only occur when the inflammatory process has extended to the parietal peritoneum, as Mr. John Morley would have us believe? There are powerful arguments on both sides, and convincing proofs that one or other of these mechanisms does not exist is wanting. That some other condition is present in the obscure

SPECIAL ARTICLES

AN INVESTIGATION INTO THE MORTALITY IN MATERNITY HOSPITALS

AND THE INFLUENCING FACTORS.*

By J. M. Munro Kerr, M.D. Glasg., F.C.O.G.,
REGIUS PROFESSOR OF MIDWIFERY IN THE UNIVERSITY OF GLASGOW;

AND

Hector R. MacLennan, M.B. Glasg.,
LATE REGISTRAR AND SENIOR RESIDENT OBSTETRIC OFFICER, ROYAL MATERNITY AND WOMEN'S HOSPITAL, GLASGOW.

The Departmental Committee on Maternal Mortality and Morbidity introduced into their Interim Report the results of a novel and interesting investigation made by a special subcommittee. This subcommittee attempted to determine in the fatal cases investigated throughout the country the reason or cause of death, or as Eden[1] puts it, "they endeavoured to pick out the point at which in their judgment the management of the cases had first gone wrong." This they termed the "primary avoidable factor."

We have been so impressed with the objective of the subcommittee in the investigation they undertook, that we have made a very thorough investigation of all the fatal cases in the Glasgow Royal Maternity Hospital for the years 1926–1930 inclusive. We feel that an investigation of this character, confined entirely to the various aspects of institutional mortality, might shed further light on the broader problem of the national maternal mortality.

The fatalities analysed represent the total deaths in the practice of the hospital, for we have included not only the deaths in hospital but also through the assistance of the Department of Health we have been able to follow up the cases of sepsis which were transferred to the fever hospitals and died there. At the outset it is necessary to mention that the number of abnormal cases admitted to the hospital is exceedingly high. In 1926, 58 per cent. of the admissions presented abnormal features. The numbers rose steadily until in 1930 the abnormal admissions constituted 70 per cent. of the admissions.

TABLE I.

Showing the number of cases treated by Cæsarean section and forceps, and the number of cases of accidental hæmorrhage, placenta prævia, and eclampsia.

Year.	Cæsarean section.	Forceps.	Eclampsia.	Accidental hæmorrhage.	Placenta prævia.
1926	125	260	69	115	86
1927	112	239	86	103	66
1928	127	226	75	131	89
1929	101	290	93	83	84
1930	184	297	59	112	94
Totals	649	1312	382	544	419

It will be observed from this table that the incidence of various abnormality is high in the Glasgow Royal Maternity and Women's Hospital. This should be considered when the maternal mortality-rate is being discussed.

Tables I. and II. briefly indicate the extent of the work undertaken by the hospital which is run on the unit system by a visiting honorary staff.

TABLE II.

Giving a summary of the total deaths in the different categories, including deaths in cases transferred to fever hospitals on account of puerperal sepsis.

Year.	Categories. A. Total. Cases.	Deaths.	Per cent.	B. Total. Cases.	Deaths.	Per cent.	C. Total. Cases.	Deaths.	Per cent.	Total. Cases in hospital.	Deaths.	Per cent. in all categories.
1926	1785	27	1·5	1226	60	4·9	642	10	1·6	3653	97	2·7
1927	1616	19	1·2	1521	70	4·6	765	8	1·0	3902	97	2·5
1928	1612	22	1·3	1496	79	5·2	833	7	1·8	3941	108	2·7
1929	1347	13	0·9	1671	88	5·2	823	13	1·6	3841	114	2·9
1930	1790	23	1·3	1934	85	4·4	745	12	1·6	4469	120	2·7

Table II. shows the total deaths in the following categories.

A.—Cases under some antenatal supervision, although in many cases this could not be considered adequate.

B.—Emergency cases sent in by doctors or midwives or students working in the outdoor department. Relatively few of these had any adequate antenatal supervision.

C.—These were women who applied for admission without being seen by doctor or midwife. They were not under antenatal supervision.

The results are very far from satisfactory, especially in category B. It is dreadful to think that the mortality-rate in this group is higher than for most abdominal operations.

TABLE III.—*Showing Cases Moribund on Admission.*
Years 1926–1930.

—	Categories. A. 1926	1929	1930	B. 1926	1927	1928	1929	1930	C. 1929	Total (60).
Obstetrical complications	1	—	—	3	1	—	1	1	—	7
Accidental hæmorrhage.	—	—	1	1	—	4	4	3	—	13
Placenta prævia ..	—	1	—	1	2	—	1	2	1	8
Post-partum hæmorrhage	—	—	—	3	—	2	—	6	1	12
Toxæmia pregnancy ..	—	—	—	8	3	1	2	1	—	15
Pulmonary complications	—	—	—	1	1	—	—	—	—	2
Abortion ..	—	—	—	—	1	—	—	1	—	2
Miscellaneous .	—	—	—	—	1	—	—	—	—	1

No fatal cases were recorded in categories A in 1927–1928, and in C in 1926, 1927, 1928, and 1930. As the total deaths occurring in hospital during the five years was 536, the 60 cases accounted for in this table represent 11·1 per cent. of the total. Further, it will be observed that the deaths with relatively few exceptions occur in patients who had received little or no antenatal care. We also consider that faulty judgment in treatment must be regarded as a potent factor in causing these deaths.

To determine the primary avoidable factor in the institutional deaths was now our task. As Table II. included all cases which died under our roof, it was

---

* Based on the Indoor Practice of the Glasgow Royal Maternity and Women's Hospital for the years 1926–1930 inclusive.

[1] Proc. Roy. Soc. Med., 1931, xxiv., 401.

They suggest that dust from the flat brush and comb could be reduced by slowing down the brush, and that when a stripping brush is used on a vacuum stripper it should be provided with a cover connected to an exhaust. They would prohibit wafting altogether, and insist that respirators should be worn by all workers removing dust or dirt from the engines or machinery. They recommend that a card-room should be ventilated by a downward draught, to keep the finer particles below breathing level, and they think it desirable that no person suffering from respiratory abnormality should be employed in a card-room. Periodical medical examination would also weed out those who were particularly susceptible to dust or who had become partially affected by it.

Perhaps the most important piece of information that emerges from this careful report of a difficult and complicated investigation is the discovery of histamine in the dust, for, if this substance be present, no method of ventilation at present available can be relied upon to protect the workers. The committee draw attention to the importance of further immediate exploration of this problem.

THE ALPS FOR BIRMINGHAM CHILDREN.

WHEN Mr. Christian Kunzle, head of the firm of C. Kunzle, Ltd., chocolate manufacturers, was last week elected president of the Birmingham Children's Hospital, he announced a scheme he had in mind for giving ailing children the chance of an Alpine cure. Mr. Kunzle now owns the château in his native valley of Davos, originally built by Mr. Buol on the sunny slopes of the Dorfberg and Schiahorn, the greater part of which are included in the estate, and for some years has envisaged the possibility of its use on a large scale as a convalescent resort for weakly people of the hospital class. With this in view, he has gradually bought land in the neighbourhood of his château, and he is prepared to give building sites on this estate for convalescent homes or sanatoriums to house those who are unable to pay for accommodation in existing institutions. Many of his work-people have already enjoyed a holiday in the château, and now to demonstrate the beneficent possibilities of Alpine residence for children to his fellow citizens in Birmingham he has placed at the disposal of the hospital for a period of two years the ground floor and dependance of the château, to which a play and school room and verandahs are being added, providing accommodation for 25 to 30 children and five nurses. The first group of children, which will leave Birmingham on May 26th next, is to consist chiefly of ambulatory cases of asthma, chronic bronchitis, mild pulmonary fibrosis and bronchiectasis, glandular tuberculosis, tuberculosis contacts, children convalescent from a long illness, such as osteomyelitis or empyema, and perhaps a few cases of bone or joint tuberculosis. These children will remain in Davos for a period of three months or longer, and if the experiment proves successful it is intended to establish a permanent branch of the hospital at Davos, either by the purchase and adaptation of an existing house, or by the erection of a new one. In that event the hospital would appoint a resident medical officer; for the present Dr. J. L. Burckhardt, head of the Children's Sanatorium at Davos, has consented to undertake the medical supervision of the children. The cost of the experiment is estimated at £2000 to £3000 a year, some part of which may be requited by the parents or the interested local authority; the Benevolent Fund of C. Kunzle, Ltd., has undertaken to defray the cost of transport of the first batch of children and the entire cost of their keep for three months. Should there be any vacancies children may be accepted whose parents can pay some part at least of the cost of maintenance.

ROYAL MEDICAL BENEVOLENT FUND.

AT the annual meeting of the Fund, held on Tuesday last, the income for the year was reported to be the largest since its foundation, and as a result it had been possible to help a larger number of persons whose circumstances obliged them to seek assistance. There is welcome evidence that the increase is due to the fact that the Fund is receiving support from a wider field, and that its existence and utility are becoming more generally known. In 1921 the income from subscriptions was £3801, while in 1931 the income from the same source amounted to £10,682, an increase of £6881. The income derived from investments increased during the same period from £4107 to £6956—namely, by £2849. The amount of financial help which the Committee have been able to give amounts in all this year to *£14,843*, as against *£7292 in 1921; this* does not include a grant of £224 18*s*. to annuitants under the Barr-Meadows bequest. But in spite of this increased income it has not been possible to meet all the claims made upon the Fund, nor to cover the distress whicl is known to exist. Appeal is accordingly again mad to every medical man and woman to become an annua subscriber. Each year personal appeals are writte by the Committee of the Fund to members of th profession in various parts of the country. Durin 1931 appeals made in Ashford, Barnstaple, Blackpoo Bognor Regis, Canterbury, Exmouth, Falmoutl Folkestone, Grays, Horsham, Lewes, Liverpool, New quay, Penzance, Ramsgate, Sidmouth, Swindo *Taunton, Tonbridge*, Tunbridge Wells, Wincheste Battersea, Harley-street, Putney, and Wandswort brought in £93 8*s*. A special appeal was also mad to British medical men and women living abroa which brought in £82 10*s*. 6*d*. Most of th response was in the *form of subscriptions*, whic will be renewed annually. The cost of thes appeals was £38 6*s*. The Christmas appeal mad by the President realised £220 18*s*. 6*d*., a larger su than in any previous year. The cost of this appe was £3 18*s*. The committee fear that the comin may be a very difficult year, and they expre the hope that each subscriber will get at least o doctor friend to give an annual contributio Especially would they like to see greater suppo coming from the younger members of the medic profession.

A word of gratitude is given in the report to tl whole-hearted and invaluable coöperation of tl Ladies' Guild which collects funds of its own distribute in grants for education and maintenanc the worth of which it would be impossible to exa gerate. After adoption of the report and financi statement Sir Thomas Barlow was re-elected Pres dent, Sir Charters Symonds hon. treasurer, S Percy Sargent and Dr. Lewis Glover hon. secretarie

Mr. F. J. Steward has been elected representati of the Royal College of Surgeons of England upon tl General Medical Council, in succession to Sir Holbu Waring.

While inadequate antenatal care has been indicated as playing such an important part in the conditions referred to, it is obvious that this primary factor may adversely affect any type of obstetric case; this is evidenced by the remaining cases which fall into the group.

II. NEGLIGENCE OF PATIENTS AND FRIENDS.

The second group which deals with cases where gross negligence is the primary avoidable factor is a much smaller group but by no means an insignificant one: 38 out of 466 (8·1 per cent. of the fatal cases) were due to this factor. The preponderance of abortion is striking. There are 13 cases out of the total of 38 in the group (34·2 per cent.). From the other aspect, 13 out of a total of 26 fatalities from abortion were a result of the patient's negligence. It is notorious that patients neglect to intimate the onset of abortion. Social, economic, and occasionally criminal reasons exist for this neglect.

The Glasgow Royal Maternity and Women's Hospital admitted 3453 cases of abortion in the five years under review. There were 26 fatal cases, 18 of which died from septicæmia. There can be no doubt that the admission of large numbers of cases of abortion presents additional difficulties in the administration of a hospital whose primary duty is to care for the parturient woman. The large numbers requiring treatment tend to cause overcrowding. Further, the majority of obstetricians consider such cases a possible source of puerperal infection. The League of Nations statistical report on maternal mortality stated[2]: "As a cause of maternal deaths it (abortion) has become more important than delivery at term."

The other cases in this group are those in which gross symptoms presented themselves and were neglected by the patient. Better education of the public to the grave dangers of neglect in pregnancy would seem to be the only solution for this type of case.

III. FAULTY JUDGMENT AND/OR TECHNIQUE.

Under this heading are grouped 66 out of the total of 466 institutional fatalities (14·1 per cent.). Again this figure (14·1 per cent.) is minimal, as we were unwilling to consider a fatality as preventable except where the judgment and technique showed some definite departure from established practice. It would be invidious to apportion blame in this group to any one source; suffice it to say that midwives, general practitioners, and obstetric specialists being fallible contribute to institutional fatalities by their occasional errors in judgment. In this respect it is our opinion that wherever possible the grosser abnormalities of pregnancy and the difficulties of labour should be treated in an institution, where the greatest facilities are available for adequate treatment of the case. It is obvious that where such treatment is necessary, the earlier the case is in the hands of the institution the greater is the possibility of success. Putting aside personal skill, it is absolutely essential to refrain from difficult obstetric operations in inadequate surroundings. The force of these observations can be readily understood by reference to Table IV., where it will be seen that obstetrical complications and puerperal sepsis comprise the greater part of the fatalities due to faulty judgment and technique.

IV. INTERCURRENT DISEASE.

Turning to the question of intercurrent disease (often unavoidable), there were 64 cases out of a total of 466 (13·7 per cent.) in which intercurrent disease was the primary factor. The cardiac cases (36) constituted 62 per cent. of the group. It is only with the most constant supervision (in hospital if necessary) that any improvement can be made in the fatalities from these cases.

V. UNAVOIDABLE DISASTERS.

Having referred in some detail to the cases in which an avoidable factor was present, we find that there are still 133 cases out of a total of 466 (28·5 per cent.) in which we can find no avoidable factor. That is to say, the antenatal care of the patient was satisfactory, there was no evidence of negligence or intercurrent disease, and the management of the case showed no departure from established practice. Yet these women died.

By far the largest proportion of these cases are those which died of puerperal sepsis, 42 out of 133 (31 per cent.). Where every care has been taken of the pregnant and parturient woman, and where despite that care the patient develops puerperal sepsis, we must in our present state of ignorance of puerperal sepsis consider the case as an unavoidable disaster. Fourteen of the obstetrical complications and 15 toxæmias of pregnancy died despite every reasonable precaution having been taken; again we consider these deaths to be unavoidable. Of the other cases in the group the same might be said.

The Departmental Committee on Maternal Mortality and Morbidity find that in 52 per cent. of the deaths which they investigated no preventable factor actually emerged. With regard to these cases they state definitely that a fuller knowledge of the exact circumstances of death would probably have revealed a primary avoidable factor. We are fortunate in our investigation in having a full knowledge of the exact circumstances of all the deaths we quote, and it is our considered opinion that 28·5 per cent. of the deaths were unpreventable. Thus by our investigation we have been able to reduce the figures representing unpreventable deaths from 52 per cent. to 28·5 per cent. When our knowledge of the ætiology of puerperal sepsis is more exact, and a satisfactory method of treatment is evolved, this figure will be still further lowered. To suggest, however, that maternal mortality can be reduced below a certain level would only create a false impression in the mind of the lay public, and saddle the medical profession with an impossible task.

The Institutional Problem.

To concentrate more particularly on the institutional problem we venture to suggest that the following additional factors play an important part:

(a) Type of case admitted.
(b) Nature of the population served by the institution.
(c) Organisation of the institution.

The mortality and morbidity-rate of institutions such as our own which admit any type of emergency as, for example, the "failed forceps" and the "incomplete abortion," will naturally be relatively higher than that in institutions which deal almost exclusively with the booked case. We stress this point, as the Departmental Committee (Interim Report, paragraph 202) in quoting the excellence of the results in certain institutions fail to specify the type of case admitted.

The nature of the population served by the institution undoubtedly affects the mortality-rate. Where the population served by the institution is afflicted with disease such as rickets (or exophthalmic goitre, Rhine valley), or where the population is composed first necessary to adjust this table by deleting from it those cases which were moribund and in a hopeless condition on admission. Those cases (60 in number) which were admitted to hospital moribund, and who died within six hours of admission without active treatment being possible, are deleted from our ultimate consideration of institutional fatalities. (Table III.)

---

[2] League of Nations Monthly Epidem. Rep. R.E.140, July, 1930.

It is our opinion that many of these cases would have been better to have been treated in their own homes. A patient who is suffering from a marked degree of shock, or one who is exsanguinated from post-partum hæmorrhage, is often rendered more seriously ill by her journey in an ambulance from home to hospital.

When a patient in the outdoor practice of the hospital requires assistance and is yet too ill to be removed, the house surgeon in charge has access to services of a senior assistant on the staff, whose duty it is immediately to attend the patient in her home. It would be of advantage if those in private attendance on similar patients to the hospital ones, and faced with similar obstetric emergencies, had the same access to obstetric specialists as do the house surgeons engaged in the hospital outdoor practice.

In Glasgow the public health authorities have already drawn up a roster of obstetric specialists who may be called as consultants to puerperal cases. It is only a step further to institute a "flying squad" of obstetric specialists to deal with urgent intrapartum emergencies which, owing to their nature, are unsuitable for transfer to an institution.

Causes of Death.

Having made the above-mentioned adjustments, we have investigated the fatalities which occurred in the institution from the point of view of the primary avoidable factor.

As far as we can judge, the death-rate of an institution is influenced by the following conditions: (1) Antenatal care. (2) Negligence of patients and friends. (3) Judgment and technique of operators. (4) Complication by intercurrent disease. (5) Unavoidable disasters of pregnancy. These conditions correspond in part to those mentioned on p. 24 of the Departmental Committee's Report. It is now our intention to classify the fatal cases as far as possible under these headings. (Table IV.) The first and second headings, Inadequate Antenatal Care and Negligence of Patients and Friends, require some explanation, as they are difficult to differentiate. Inadequacy of antenatal care results from several causes: (*a*) insufficient available clinics, (*b*) faulty organisation and administration of these clinics, and (*c*) ignorance or neglect on the part of the patient and her friends. The first two factors we do not propose to discuss, as they are rapidly becoming corrected by maternity institutions and local authorities. In our analysis-of-the preventable factors, where there has been evidence of obvious antenatal errors in diagnosis or treatment, the fatalities resulting therefrom have been grouped under faulty judgment and technique. With regard to the third cause of inadequacy—(*c*) ignorance and negligence of the patient and her friends—failure to seek antenatal care has only been classified as "negligence," where the *abnormality present* has been evident to the patient herself, and where the neglect of this condition has been the primary cause of her death. Similarly, where a patient has been offered treatment or advice antenatally, and where this has been *completely neglected,* we have preferred to assign the primary cause of death to gross negligence rather than to lack of adequate antenatal care.

TABLE IV.—*Primary Avoidable Factor 1926–1930.*

—	Antenatal care.	Negligence of patients and friends.	Intercurrent disease.	Judgment and/or technique.	Unavoidable disasters of pregnancy.	Total.
	Total cases, 1926–1930.					
Obstetrical complications —e.g., failed forceps, &c.	15	3	0	26	14	58
Accidental hæmorrhage..	4	2	1	0	4	11
Placenta prævia	16	3	0	0	11	30
Post-partum hæmorrhage	1	0	1	2	2	6
Puerperal sepsis ..	13	3	3	29	42	90
Toxæmias of pregnancy ..	109	12	0	4	15	140
Heart disease	0	0	36	0	0	36
Pulmonary complications	1	1	13	0	4	19
Embolism and thrombosis	0	0	1	0	10	11
Abortion	0	13	0	3	10	26
Miscellaneous causes ..	6	1	9	2	15	33
Anæsthetic deaths ..	0	0	0	0	6	6
Totals	165	38	64	66	133	466

This table excludes ten cases who died of puerperal sepsis after transfer to fever hospital. Data concerning them was insufficient to assess avoidable factor. They have been already shown in Table III. and included in our totals.

I. INADEQUATE ANTENATAL CARE.

It will be seen that inadequate antenatal care was as far as we could judge, the primary avoidabl factor in 165 out of the total of 466 institutiona fatalities (35·3 per cent.). This figure is minimal, a cases were grouped under this heading only wher the cause of death could be definitely assigned to pathological condition, which could have been rectifie or considerably ameliorated by prenatal care.

It is worthy of note that toxæmias of pregnanc constitute by far the greatest proportion of thi group—109 out of a total of 165 in the group ar toxæmias of pregnancy. That is to say, toxæmia of pregnancy constituted 66·5 per cent. of the fat cases where inadequate antenatal care operated a the primary avoidable factor. Viewed from anoth angle it will be observed that there were 140 fataliti in all from toxæmia of pregnancy and 109 of thes (77·8 per cent.) were due to lack of antenatal care.

Considering placenta prævia in the same way will be seen that this condition counts for 16 out 165 (9·7 per cent.) of the group. Also, that of th total of 30 fatalities from placenta prævia, 16 (53·3 p cent.) were *due to inadequate antenatal* care. In a these cases premonitory symptoms of placenta præv (slight hæmorrhage) occurred antenatally, and ha they been given due consideration at the time it more than probable that a fatal issue could hav been averted.

We would draw attention also to the 13 cases puerperal sepsis which we have included in the fir group. These cases presented abnormalities whic might have been corrected. This necessitated co siderable interference in labour. We discussed ver carefully together the grouping *of these cases.* W have included them under Group I. and not und Group III. (Faulty Judgment. &c.) because of ou desire to stress the point that a resultant puerper sepsis may be on occasion due to lack of antenat treatment.

udge and jury, why cannot solicitors reach a settlement in these cases without instructing counsel? t is remarkably unfortunate for a professional man who is defendant in this class of case if it be true hat a plaintiff is not in the frame of mind to examine he merits of the defendant's answer until the claim as been begun before a court of law and all the llegations have been broadcast to the world.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

HOULD NERVOUS CHILDREN BE TAUGHT IN SPECIAL INSTITUTES?

In a recent lecture Dr. O. J. Vértes, director of the National Secondary School for Nervous Children, stated his conviction that in cases of severe nervousness in children the only solution is the removal of the child from home. The patient at his new abode behaves timidly and awkwardly at first, but as soon as he realises that he is among understanding people he settles down. The causes which gave rise to symptoms are removed with the change of residence. The jealously guarded cherished child becomes aware of the fact that he is not the centre of the world, and that others have just as much right to consideration as he has. It is important that the parents should not visit their children too often. This advice sounds so simple that one might conclude that the despatch of the child to a good aunt's or grandmama's house would yield beneficial effects. This is, however, not so. The education of a nervous child needs trained experts, or the child becomes just as tyrannical in his new environment as he was at home. Besides apparent (not real) neglect, important curative agents are a systematic day's routine and instruction in how to work. The child should not be bored for a single moment, and should not have too much time for meditation. In the critical post-war years the number of nervous children increased greatly. These children have to be discovered and appropriate schools found for them. In Budapest the number of children educated in special secondary schools for nervous ailments is 1200.

INVENTION FOR IMPROVING THE QUALITY OF FLOUR.

D. Kuffler invented a method whereby the quality of flour is greatly improved and rendered suitable for patients suffering from dyspepsia and other digestive troubles. The invention—a biochemical process of heating the flour to a very high degree without burning or roasting it—is patented. The flour is conducted through a boiler containing superheated dry air, whereby it loses its water content and one-third of its sugar content, and—as proved by investigations made by the Royal Hungarian Cereals and Flour Experimental Station—the formation of carbonic acid diminishes to a tenth. This purified flour is particularly easy to digest, and causes no heartburn or meteorism even in patients suffering from serious gastric and intestinal troubles: it is said also to have a favourable influence on all disturbances arising out of hyperacidity. This so-called "dietetic flour" is at present stocked in Hungary only by chemists, but it is shortly to be marketed by grocers so that the general public will be able to procure it easily. It is said to suffer no change in the process of overheating, so that the foods prepared from it are undistinguishable in taste from those made with ordinary flour; the only difference is in the colour, which is darker than that of ordinary flour. Some of the Budapest clinics and hospitals have used this flour with success in the diet of patients suffering from gastric and intestinal disturbances.

ASPIRIN POISONING IN HUNGARY.

While aspirin poisoning appears to be rare abroad, in Hungary it is of common occurrence, mostly in suicide cases. The Budapest Ambulance Corps rendered first aid to 230 aspirin suicide cases in 1927, to 206 cases in 1928, and to 154 cases in 1929. The symptoms of intoxication are: vomiting, syncope, photophobia, tinnitus, and general malaise of a fairly severe degree. The pulse-rate is accelerated. The urine contains albumin and occasionally also traces of blood. The number of red blood-cells is diminished, while the quantity of hæmoglobin does not undergo any considerable change so that the condition is that of a toxic polychromæmia, with slight leucocytosis. The sedimentation rate of the blood is normal and blood pressure is slightly diminished. The poisoning takes a fairly rapid course; *if there is no improvement noticeable within* 12 *hours from the onset of symptoms, acid intoxication supervenes. The respiration becomes deep and slow, the heart's action becomes weak, and death* follows paralysis of the respiratory and of the cardiac centres. The routine treatment, as applied by the Budapest clinics, consists of gastric lavage with a well-diluted peroxide of hydrogen solution, or with bicarbonate of soda. Emetics are not recommended. Intestinal irrigations with large doses of bicarbonate of soda, repeated every two to three hours or so until the urine becomes alkaline in reaction, may be of benefit.

PHYSICIANS AND LAWYERS ON BIRTH CONTROL.

The medico-legal section of the Hungarian Social-Democratic party recently held a debate. In his opening address Imre Gyürki remarked that the increase of population to-day is an economic question, and the regulation of births is one of the most important problems of the present age. It is in vain that a great many of those who most vigorously fight in support of the percentage norm in the universities, in respect to those living, protest even against the thought of planning the regulation of births. Dr. Bela Tóth emphasised the fact that medical science is concerned also with social science. The fate, health, and disease of the individual must depend on the social conditions among which he is living. The existing law lays down that only danger to the life of the mother justifies birth control. Danger to the mother, however, may include not only danger of death, but also the reduction of capacity for work, and the dwindling of earning power. In the decision of this important problem the high infant mortality-rate, the housing conditions, and other social problems, such as the prevalence of induced abortions, must be considered. In Hungary the number of induced abortions is estimated at about 100,000 out of a total population of seven and a half millions, and the large majority of cases come from the industrial and agricultural classes. In 1925, 115 sentences were passed against those who attempted to procure abortion, but much more serious was the punishment of those who paid for the operation with their lives. From the statistics he has collected Dr. Tóth estimates the casualties due to induced abortion as 700–800 yearly, and the number of women who are affected with lasting bodily or mental troubles due to abortion as about 10,000. Dr. Latkóczy quoted the opinion of Magnus Hirschfeld, the sexuologist, that out of 1000 cases only three are brought

MEDICINE AND THE LAW.

Criminal Abortion.

Two men pleaded guilty at the Leeds Assizes on Feb. 29th to charges of manslaughter and of performing an illegal operation. The victim was a married woman. Last October, being then a widow with seven children, she re-married. Expecting again to become a mother, she arranged with one of the accused men that she should be operated on at his house by the other of them. She collapsed during the operation; whereupon the two men, with unspeakable callousness, dragged her out of the house in a dying condition and left her by the roadside where her body was eventually found. Mr. Justice Humphreys sentenced the man who had performed the operation to five years' penal servitude and his accomplice to 18 months' hard labour.

It may be hoped that the case may find its way to the Court of Criminal Appeal for the sake of additional publicity and in order that the Court may have an opportunity to confirm Mr. Justice Humphreys' view that the offence of unlawful abortion is a grave one. Utterances by one of his colleagues have raised doubts which this case may remove. Many who regard the question as merely one of birth control do not realise that the serious element in the crime is that life and health are endangered by the inexpert and septic methods of these furtive and unlawful practitioners. Far more harm is done than is ever revealed in a court of justice. The difficulty of obtaining evidence is notorious, and nobody imagines that the number of prosecutions represents any serious proportion of the number of offences. The accused man who conducted the operation in the Leeds case was a weaver, aged 41; his companion was a wool teaser, aged 62. As the learned judge pointed out, women seem shockingly ignorant of the terrible risks they run by putting themselves in such persons' hands. The judge observed that counsel for one of the men had spoken of the ethics of abortion, "whatever the ethics of such a crime may mean." "But," he added, "it is no part of the duty of a judge trying a case to discuss the ethics of an offence which is a crime under the laws of the country."

Notification of Diseases and Confidentiality.

In the columns of our contemporary the *Medical Officer,* a correspondent has lately raised a point of great public importance. He states that, where persons have recently died from tuberculosis, the agents of life insurance companies or societies are, in some cases, calling at the office of the local public health department or tuberculosis clinic and asking for information as to the date on which their disease was notified. When this information has been refused, there has been a renewed request, accompanied by the statement that such information is given quite readily in other towns. As the writer of the letter justly observes, there is no desire to connive at the malpractices of persons who make fraudulent declarations on entering insurance; but, unless a cynical view is taken of the word "confidential," it is a duty to refuse to give the details asked for, except under the protection of the courts.

Article II. of the Public Health (Venereal Diseases) Regulations, 1916, contained the express direction, reinforced by a departmental circular, that "all information obtained in regard to any person treated under a scheme approved in pursuance of this Article shall be regarded as confidential." The Public Health (Tuberculosis) Regulations of 1930 do not contain a similar stipulation, but they leave no doubt that secrecy is to be observed. Like previous Regulations for the notification of infectious disease, they require the notification to be enclosed in a sealed envelope; this requirement, it is added, will b sufficiently complied with if the notification is folded and sealed "in such a manner that during its transmission the particulars of the notification cannot b observed." Why this precaution if on arrival th communication may be divulged to anyone who asks Insurance companies are entitled to full disclosure *information affecting the contract of insurance* but the duty is owed only by the person with whom th contract is being, or has been, made; the officer of public health department is in no way the agent representative of an insured person for the purpo of being affected by this duty. The whole system notification of infectious diseases is a statutory brea of the medical rule of secrecy; the relaxation of t rule is strictly limited to the statutory requiremen the fact that a patient suffers from a notifiable dise does not mean that thenceforth there is no furtl duty of secrecy. If the Ministry of Health reali the danger which our contemporary's correspond has revealed, it will doubtless take steps to make cl *that notification is at all stages a* confidential mat

Alleged Negligence: Another Plaintiff Withdraws.

In Tudor *v.* Mein, discussed in these colu *last week, an allegation of professional* neglige launched against a surgeon, was withdrawn a hearing the evidence of the defendant and tw his expert witnesses. A somewhat similar settlen of litigation, on learning what could be said on other side, occurred at about the same date in Supreme Court of Northern Ireland. A schoo at Campbell College, Belfast, had been inj accidentally by a blow from a spade while hel to level the school football field. The injury followed by septic poisoning. Treatment pr difficult; it was said that the boy had been atte by 35 doctors, had undergone 26 operations, and been five years on his back and was not well The boy and his father brought an action for dam against the governing body of the school for all negligence. After the plaintiffs' case had opened and Sir Thomas Houston had given evid in support of it, the evidence of a second wi was interrupted by counsel announcing tha settlement had been reached. Allegations of n gence against the matron (who had treated the injuries) and the headmaster respecting the ge conduct of the school were withdrawn, and defendants agreed to make a payment to the and his father as part of the settlement.

In Tudor *v.* Mein the revelation that there two sides to the case and that the defendant h satisfactory answer to the allegations of neglig occurred after hearing the defendant himself. I Belfast case the revelation came earlier through defendants' counsel allowing the plaintiffs' co to read the proofs of the medical and other witn who would have given evidence for the defend The same question suggests itself as in Tudor *v.* why cannot means be found to convince plai at a still earlier stage that there is an adequate an on the defendants' behalf? A great deal of money, and anxiety would be saved if such a disco could be made before the briefs are delivered counsel can satisfy one another by a mutual discl of facts and opinions without leaving the decisi

CORRESPONDENCE

MEDICAL PATENTS.

To the Editor of THE LANCET.

SIR,—I read with interest the leading article on he Law of Medical Patents in your last issue. It eems to me that the issues at stake are of national mportance, and should not be left to vested interests r Government departments to determine. Research orkers who are in receipt of salaries or scholarships, r who are employed on a whole or part-time basis, re in a category of their own, and are surely not ntitled to exploit any discoveries they may make r their own benefit. The benefit of their inventions hould logically be vested in those who have provided he means for their discovery.

The position of the private or independent research orker is different. He has to bear the whole cost f his work, and is in an unfavourable position should e make a discovery which is patentable. To deny im such rights would be to hinder valuable research, r alternatively to drive such successful inventors o seek patent protection for their inventions in some oreign country first, afterwards obtaining similar rotection in the United Kingdom through the onvention. This could not be prevented except in he unlikely event of unanimous international agreement upon the subject of medical patents.

My own case may throw some sidelights upon the question. A good many years ago I was investigating the effect of ultra-violet radiation not only upon the human subject but also upon foodstuffs and other substances. I had previously come to the conclusion that the value of "food" depends not o much upon its quantity or "calorific" content as upon the presence of "living substances"—the so-called vitamins. It seemed to me that the enormous importation of "preserved" food into this country was leading to a steady deterioration of the physique of the race, a deterioration which was naturally most felt amongst the masses of the people. The results of my researches led to several discoveries which I made no attempt to patent or keep secret. Whilst I, *at my own expense*, was testing the effect of certain of these preparations in the out-patient department of a London hospital, I was approached by a representative of a firm which had purchased the patent rights in this country of the Steenbock invention to test their preparations. My feelings may be well imagined, particularly as my own preparations proved clinically superior to those of the firm in question. These conclusions were independently verified by a number of qualified clinical assistants working with me.

Some years later I mentioned this matter in conversation, and was urged to try to obtain a patent even at this late stage. I did so, and was granted protection last December (British Letters Patent, "Treatment of Yeast," No. 354371). The Steenbock patent however, being so wide and comprehensive in its claims, is regarded by many as a "master patent."

The effect of my patent would be that, if commercially exploited, substances containing vitamins B1, B2, and D could be made and sold at such a price as would place them within the reach of every man, woman, and child in this country who needed them. But up to the present no firm has shown the intention either to benefit themselves, the nation, or the inventor, as they appear to be in awe of the Steenbock patentees. I have been informed by more than one person who could speak with authority that the Steenbock patent might not survive the acid test of the English law courts, but that no one would care to oppose the patent in such a manner because the rights are held by a University!

One is almost forced to the conclusion, Sir, that much of this talk about medical patents is unpractical, and does not offer any real solution of the actual problems. These problems are surely national, and demand the attention of statesmen.

I am, Sir, yours faithfully,
PERCY HALL.

Gloucester-place, W., March 14th, 1932.

To the Editor of THE LANCET.

SIR,—In the discussions surrounding the application of the patent laws to medical discoveries it is essential not to lose sight of certain fundamental principles: (1) It is less important to prevent a doctor making anything out of a process which he has invented than to make sure that patients are protected from spurious remedies. (2) If there is a chance of making money out of a thing people will make it despite any form of legislation or regulation or ethical convention. (3) If a man has devoted a great deal of his life, and perhaps some of his money, to the development of a process, even though it be for the relief of sickness, he is going to make whatever he can out of it. (4) A manufacturer is not going to put down expensive plant, employ trained men, and pay for publicity unless he can be guaranteed protection; in other words, he will not really make an effort to market a product unless it is patented. Most sensible people agree with these points when speaking in camera. The doctor admittedly works primarily for the relief of sickness and suffering, but it is merely cant to pretend that he is concerned only in the very far background of his mind with thought of his daily bread and butter and with the upkeep of his home and the education of his children.—I am, Sir, yours faithfully,

March 15th, 1932. GENERAL PRACTITIONER.

ARTERIAL ATONY AND ARTERIO-SCLEROSIS.

To the Editor of THE LANCET.

SIR,—I should like, if I may, to reply briefly to Dr. A. Abrahams, writing in your issue of Feb. 27th (page 480), who, unlike your annotator, has failed to understand me aright; for by the term "athletes" I understand persons of constitutionally large size who make the topmost physical achievements, requiring not only single muscle groups, but the whole bodily musculature. Not in the remotest degree did I wish to bring arterio-sclerosis into ætiological relation with the ordinary gymnastic exercises or the moderate activity in sport which is so important for everyday health. If Dr. Abrahams reads this into my article I think he does me wrong. I will gladly admit that I expressed myself in my original work too shortly for Dr. Abrahams, and I see myself obliged to prove with some figures that excessive bodily work is an important ætiological factor in the occurrence of arterio-sclerosis.

For instance, I find in the statistical tables of Braun[1] percentages of raised mortality up to 267 before the law. This means that the law, in its present form, is inadequate and non-executable. The law means well, but results are disappointing.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

ROYAL VICTORIA HOSPITAL TUBERCULOSIS TRUST.

THE forty-fourth report of the Trust contains legitimate expressions of satisfaction that the Trust was directly inspired by the discovery of the tubercle bacillus some 50 years ago. It is common knowledge that Sir Robert Philip studied tuberculosis at that date in Vienna, bringing back to Edinburgh an enthusiasm for the investigation and treatment of tuberculosis that has never wavered. Step by step, the group of institutions for which the Tuberculosis Trust is responsible came into existence and had a notable effect in developing the tuberculosis policy of this country. In a recent appreciation contributed to the *Zeitschrift fur Tuberkulose* (Berlin) Sir Robert Philip says that all that has been attempted in Edinburgh, in relation to the problem, was inspired by the stimulus produced by the completeness and the beauty of Koch's demonstration. It was the realisation of the extent of the damage wrought by the bacillus which led to the foundation at Edinburgh of the Tuberculosis Dispensary (1887) as a receiving house and intelligence centre where information would be received and guidance given concerning the disease. Thereafter came the establishment of the Sanatorium (1894) followed immediately by the School for Tuberculous Children (1895), the opening of a pavilion for advanced consumptives by the municipality (1906), the inauguration of the Farm Colony for more continuous care (1910), the provision of a classroom and laboratory for the teaching of medical students and doctors (1912), the establishment of the chair of tuberculosis in the University of Edinburgh (1917), the opening of the Sanatorium Colony, Southfield (1922), and the establishment of a tubercle-free herd of cattle (1923).

EDINBURGH ORTHOPÆDIC CLINIC.

In January, 1931, a clinic which had been formed in 1926 was formally constituted as an independent body, to be called the Edinburgh Orthopædic Clinic. The object of the clinic is to provide massage, medical gymnastics, medical electricity, and ultra-violet ray treatment for people of limited means at moderate fees. At the first annual meeting of contributors to the clinic, Miss Gertrude Herzfeld, F.R.C.S.E., presiding, it was stated that during 1931 258 patients had been admitted and 36 patients readmitted; 5899 treatments had been given, compared with 5909 treatments during the previous year. On the actual working of the clinic for the past year there was a deficit of £98; but as the revenue accruing amounted to £140, the capital fund had been increased by £41. The clinic had been approved by the Department of Health for Scotland as a charitable institution and patients insured under the National Health Insurance Scheme might now obtain benefit through their approved societies. Mr. William A. Cochrane stated that it was an up-to-date clinic and contained everything required for remedying physical defects by these special means. It was so popular now that it had a waiting-list and the work done was of the first order. An interesting feature was the home service provided by the clinic. Cripples are well served in Edinburgh. The Rev. Ratcliffe Barnett, who has taken a keen interest in promoting the new Cripple Children's Hospital at Fairmilehead, on returning from the war, started a club here for men and lads who were permanently crippled, and it is still flourishing.

CHIROPODY IN EDINBURGH.

At the annual meeting of the Incorporated Society of Chiropodists, Dr. Craig, who succeeded Dr. Drever as Scottish Medical Secretary of the British Medical Association, referred to the excellent work done by the Edinburgh Foot Clinic. During last year they had treated over 8000 people, and there was a waiting-list of 1600. The clinic made a small charge to all patients who were in a position to pay, while treating free those not able to pay. Dr. Craig thought the general public had little idea of the mass of suffering that resulted from the kinds of foot troubles which the clinic was able to treat, and praised the good work being done there.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

THE NEW GOVERNMENT.

THE post in the Government of the Irish Free State which is of most importance to the medical profession is that of Minister for Local Government and Public Health. It is satisfactory that this office has been given to one who has considerable experience of the problems of local government, Mr. Sean T. O'Kelly, who was for many years a member of the Dublin Corporation. It is rumoured that he may have the assistance of one of the medical deputies as Parliamentary Secretary. A medical man, Dr. James Ryan, has been appointed Minister for Agriculture.

SWEEPSTAKE MONEY FOR MEDICAL RESEARCH.

In a letter to the *Irish Times* of March 12th, Dr. Henry Moore, professor of medicine in University College, Dublin, repeats a suggestion made by him more than a year ago at a meeting of the Dublin University Biological Association. He is concerned with the lack of provision for medical research i Ireland, and he suggests that a small percentage o the fruits of the Hospital Sweepstakes might b earmarked for this purpose. He states that a capita sum of, say, £200,000, would provide a fund adequat for the financing of medical research, and that suc a sum would quickly be accumulated from even small percentage of the moneys at present bein devoted to the hospitals. He enumerates a few o the advances in medicine due in recent years t medical research, notably in the treatment of diabete and of pernicious anæmia, and suggests that expenditure on research might give results of more permanen benefit than even the improvement of the hospitals Following on Prof. Moore's letters Dr. T. P. C Kirkpatrick, general secretary of the Royal Academy of Medicine in Ireland, writes to the same journa (March 14th) to state that the General Council o that body had prepared a scheme on the line suggested by Dr. Moore, and were only awaiting suitable opportunity to place it before the Ministe for Justice, under whose control the Hospita Sweepstakes are conducted.

The sum received for tickets in the Grand Nationa Hospital Sweepstake which were drawn this wee was stated to be £3,365,312, of which £2,239,477 wil be distributed in prizes, and £841,328 be available fo the hospitals. This is an advance in the sum for the hospitals of almost £100,000 beyond that from the Sweepstake on the Manchester November Handicap, 1931.

travenous puncture. Apart from the possibility acquired immunity and sensitiveness it will be ted that there are (as with other poisons and fections) wide variations in the degree of the imary or constitutional susceptibility.

I am, Sir, yours faithfully,
J. A. RYLE.

Wimpole-street, W., March 14th, 1932.

BCG VACCINE.

To the Editor of THE LANCET.

SIR,—In your issue of Feb. 20th (p. 422) Prof. S. de Cummins has published a noble and highly ientific letter on B C G, and henceforth your readers n judge the exact value of preventive vaccination ainst tuberculosis, as it is done in France and in any other countries.

Nevertheless it seems necessary to put right certain posite arguments, invoked by Dr. W. M. Crofton a letter immediately following that of Prof. mmins. Dr. Crofton says: "It does not seem to e that any reasonable person can think the B C G ethod a desirable way to immunise human beings ainst tuberculosis." He fears the use of living cilli and prefers killed antigens. If he had himself udied these as I (and many others) have done for 30 ars, he would know that dead antigens, bacilli or cillary products, do not immunise. As for the nger of using living bacilli there is none when one es B C G, for those who studied it seriously all now that it is innocuous. It should not be forgotten at only *living* vaccines such as Jenner's small-pox mph, and Pasteur's vaccines against rabies, anthrax, al-septicæmia, yield solid and durable immunity. he *dead* vaccines used against typhoid fever, cholera, c., can only immunise for a short time and very imperfectly.

How is it possible for a reasonable person not to nderstand that it is better to immunise children mediately after birth against tuberculosis by the pregnation of their organism with surely innocuous nd permanently effective bacilli, than to wait for em to be immunised by an accidental virulent fection which may turn into a deadly illness any ay of their lives?

I am, Sir, yours faithfully,
Dr. A. CALMETTE.

Pasteur Institut, Paris, March 9th, 1932.

TUBERCULOSIS OF CHILDHOOD.

To the Editor of THE LANCET.

SIR,—I should like to thank Drs. Toussaint and MacIntyre for their very able and practical comments on Dr. Fletcher's paper, and I should like to endorse these. Dr. Kerley, however, appears to consider that they have not appreciated sufficiently recent advances in radiological technique. But has this improvement really enabled us to discover with any degree of certainty the nature of every pathological lesion in the chest which throws a shadow on the screen or plate? I think that those with a wide clinical as well as radiological experience will answer that it has not. Many of the "pneumonic conditions" in children described are either tuberculous or epituberculous in nature, with Koch's bacillus as a primary or as a secondary infecting agent, but many are not. The differential diagnosis is often very difficult, impossible usually by radiology, and only to be established on the history or the absence in the history of lassitude, failure to gain weight, and occasional slight pyrexia. The slight pyrexia, it should be added, may only be discovered on admitting the child to hospital for diagnosis. But do all cases end in complete resolution or calcification? Do not some end in bronchiectasis and in chronic non-tuberculous pulmonary fibrosis? Of those that resolve eventually some may have been non-tuberculous, and judging by the rarity of the radiological discovery of basal calcareous shadows in adult skiagrams only a few pass on to calcification. Are we even sure that no organism except the tubercle bacillus can produce such a lesion?

In your last issue (p. 597) you quote Dr. William Munro, of the Glenlomond Sanatorium, as saying, "London observers do not appear to regard pulmonary tuberculosis as a late manifestation of a childhood infection. They are wrong and far wrong. The facts are all against them." Surely this is a very sweeping statement to make. Those of us who consider that most adult pulmonary tuberculosis, especially the more acute type so prevalent among young adults, represents a recent primary or a new infection may be wrong, but the facts are certainly not all against us. Of all the evidence which Dr. Munro seems to disregard I think the most important is that of the investigations into the health of 581 probationer nurses by Heimbeck—4 out of 282 tuberculin-positives and 67 out of 299 tuberculin-negatives developed pulmonary tuberculosis during their hospital training.

I am, Sir, yours faithfully,
C. O. S. BLYTH BROOKE.
Chief Tuberculosis Medical Officer, Antrim County Council.

Belfast, March 14th, 1932.

To the Editor of THE LANCET.

SIR,—In their reference to my paper on pre-symptomatic tuberculosis in childhood Drs. Toussaint and MacIntyre raise some interesting points. The diagnosis of enlarged tracheo-bronchial glands in children is of the utmost importance, as the condition is invariably of tuberculous origin. Efforts have been made by workers in all parts of the world to make the diagnosis clinically, but as I have said, "the number of correct diagnoses is small." A good many cases are also missed radiologically, because the X ray does not show these glands until they are comparatively very large and generally caseous. But if the X ray does show them, the diagnosis is clinched, as the appearances are unmistakable. Dr. Kerley puts the position plainly. But there still seems to be a great many people who are referring to branches of the pulmonary artery as "glands" in X ray films.

There is only one important gland which anatomically could be represented at the site of the hilar shadow, and that is the large broncho-pulmonary gland. This is never seen unless it is calcified—i.e., healed. In cases of non-tuberculous lung infection, this gland is very often enormously increased in size, but no shadow is cast by the X ray. The only glands which are identified by the X ray in the pre-calcification stage are the tracheo-bronchial and para-tracheal groups.

The question of the tuberculin test is a much more difficult one. The recent report of the Medical Research Council goes into it fully and the conclusions are conservative. Although it is generally accepted that tuberculin does not sensitise to itself, I have found that children who are non-reactors to-day may be reactors to the *same* dose of tuberculin in a for those engaged in heavy work, such as copper-mining, in contrast with 0 for chauffeurs, 45 for cooks, and 35 for electro-technicians. North American statistics [2] show that big persons of excessive weight, and height of 185 cm. plus, show a greater mortality than smaller persons. And Hörnig [3] is of opinion that especially big powerful overweight persons, among whom athletes are to be included, show a higher mortality than normal persons. Braun [4] found an excess mortality of 50 per cent. for stage acrobats. Dr. Dublin of the Metropolitan Life Insurance Company has examined mortality and morbidity from heart disease among people who engaged in sport in their youth. The mortality varies much among the various sports and is greatest in baseball players and oarsmen. The mortality is 8 per cent. higher than among the usual insured population and 12 per cent. higher than among average sportsmen. What is most striking is that of those over 45 years 32 per cent. died of heart disease, whereas in insured persons the proportion is seldom more than 20 per cent. On the average those who in their youth as students have done some sort of sport live somewhat longer than other insured persons. That can only be explained by assuming that the average insured person has enjoyed a less happy youth than the student. But quite apart from this, it gives food for thought that those who have gone in for sport are appreciably more damaged in their cardiac efficiency than those who have not indulged excessively in sport.

As far as the blood pressure is concerned, the sharp rise of maximal blood pressure during work is certainly not without its effect on the vessels, but for the work of the heart it is not so much a question of maximal blood pressure as of the *pression efficace* in Potain's sense. Astel and Grosse [5] were able to establish a constant rise of minimal blood pressure, and of course also of the *pression efficace*, even during a three months' course of training. I believe that the results which have been obtained from a vast array of figures carry more weight than the few old Marathon runners who are remembered just because they are exceptional.—I am, Sir, yours faithfully,

Berlin, March 10th, 1932. JOH. PLESCH.

RESEARCH IN ASTHMA.

THE URINARY PROTEOSE.

To the Editor of THE LANCET.

SIR,—Dr. Freeman has on two occasions published statements[6] about a visit that he paid at my invitation to Guy's Hospital in order that we might together investigate the skin reactions of the proteose. Personally I should have thought that the results of such a visit should either have been regarded as confidential like the proceedings of the Asthma Research Club, of which he is honorary secretary, or if publication was desired a combined report of the results by those taking part in the test should have been written, or at any rate my permission should have been obtained before publication; this latter was not done.

Let me say that in his original communication I have not much objection to his statement of the result of the test, though it might have been more complete and the case I showed him was not specially "selected" as he presumes. His rhetorical flourishes, though highly coloured, were on the whole harmless;
but his last description of the visit certainly requires
some counter-statement, since he says that he saw
at Guy's Hospital that very small differences were
being taken to indicate a reaction, and he comments
on "the apparent lack of caution with which these
possibly chance differences were being interpreted."
I feel it only fair to Dr. Bruce Pearson, who is makin
a careful investigation of the whole subject b
injecting active and control proteose into asthmati
patients and normal subjects, to combat this state
ment. In the last number of THE LANCET ther
appears (p. 571) a short report of Dr. Pearson'
paper to the Therapeutic and Pharmacologic
Section of the Royal Society of Medicine in whic
he gives the criteria of a reaction and the conclusio
so far reached are briefly stated.

I should also like to refer to Dr. Oriel's demonstr
tion before the meeting (not noted in your column
at which five patients and two normal controls we
injected with (1) an active proteose from an asthmat
case; (2) van Leeuwen's extract of human dandru
and (3) a proteose solution from a normal patie
All who attended the demonstration noted that w
the asthmatic patient the asthmatic proteose and t
human dandruff gave positive results, whereas t
proteose controls were normal, while in the norm
subjects all three substances gave negative resul
No doubt the reactions to the proteose are not
marked as reactions to pollen, and strong soluti
of the proteose are apt to give tests in normal peo
as well as allergics. Possibly Dr. Freeman in
paper was using too high a strength of prote
solution so that nearly all his results were positive

E. P. POULTON

Upper Wimpole-street, W., March 12th, 1932.

ANAPHYLAXIS FROM BEE-STINGS.

To the Editor of THE LANCET.

SIR,—In his interesting letter on this subj
Dr. A. L. Gregg remarks that we have as yet
adequate explanation for the sudden loss of immun
to bee-stings which may occur even in veteran
keepers. I had occasion to seek an explanat
last summer when my wife, after handling bees
two or three seasons and sustaining only local reacti
of moderate severity, had the following uncomfort
experience. One day a solitary bee stung her on
scalp. Within a few seconds her eyes began
itch and she had a sensation of swelling in the
lids and the ears. This was followed by a n
unpleasant feeling of constriction in the chest
a little later by generalised urticaria. She ha
soda bath and rested and within five hours
completely recovered. We were naturally anxi
to understand the significance of this reaction
to know what was likely to happen on the n
occasion. I put the problem to my friend, Dr. P.
Laidlaw, who made the ingenious and, I beli
appropriate suggestion that the bee had administe
an intravenous sting. In support of this my
recollected clearly that there had been no l
reaction at the point of puncture. She has since b
stung with an ordinary local response. May it
be that these occasional and alarming anaphyla
seizures in persons usually immune or reacting i
local way only are due to intravenous stings? Perh
the question of "dosage" should also be consider
for the simultaneous administration of many cutane
stings might produce the same effect as a sin

PUBLIC HEALTH SERVICES

A TUBERCULOSIS AUDIT.

THE Ministry of Health has issued[1] an important port on tuberculosis written by Dr. A. Salusbury cNalty, in the prefatory note to which Sir George wman likens the Ministry's annual reports to e yearly audits of business corporations. The tlay on maintaining residential institutions for e treatment of tuberculosis, we are told, amounts 2½ million pounds, exclusive of the cost of treating ose tuberculous patients who are in public assistance spitals. And this figure takes no account of the ntrol of milk-supply, the maintenance of the spensaries, and other sides of anti-tuberculosis rk. Is the nation receiving an adequate return r such expenditure? At a time of national financial ress like the present, it is, Sir George points out, ore than ever important to know the answer to this estion. Dr. MacNalty's report contributes to this owledge. Beginning with the prevalence of tuberlosis in this country, he states that the number of aths from all forms of tuberculosis has fallen om 58,930 in the year 1901 to 37,990 in 1929. he existence of the three peaks of mortality—ung adult, middle age, and old age—foreshadowed y Brownlee in 1918 are shown to have now become fficiently marked to be demonstrable in the graphs ven in the report. One of the most puzzling atures in the statistical records of tuberculosis in ngland and Wales is the peak of mortality for the oung adult woman. The rate of decline in mortality as increased for both sexes in the middle age and ld age groups, and also in the young adult male roup, but the decline in mortality amongst the oung adult women has practically ceased. The ortality in this group is stationary at the same level s in the early days of the century. The report uggests that a secondary cause is acting at this age which is independent of the tubercle bacillus. This eems highly probable. The whole clinical picture points to the soil rather than the seed, and every phthisiologist must be seriously concerned with our failure to reduce the mortality in this group. There are not wanting signs however that the outlook for this type of case is better than it was. Earlier diagnosis is being effected and there is probably no class of case that so well repays sanatorium treatment.

On the sanatorium system in general Dr. MacNalty has assembled data from various British sources which should give a reasoned answer to those who condemn the system as wasteful and extravagant. It is not that the sanatorium system has been at fault during the last 30 years but that there has been such confusion of ideas in carrying it out. As Dr. MacNalty points out, widely different policies in selecting cases, in classifying them, in maintaining them for long or short periods, in recording results and other cognate matters of procedure, have in the past created a muddle which is only just beginning to get straightened out. In this respect we are glad to see the good results of Frimley Sanatorium stressed. The practice adopted at this institution of admitting only such cases as have been through a preliminary period of observation at the Brompton Hospital is one which public authorities might adopt with profit. Another point which should be stressed is the length of stay in the sanatorium. A discerning colleague from overseas after examining closely our English system recently expressed the view that the weakest point in our system was the shortness of the stay in the sanatorium. We are of course hard pressed to reconcile public purse and private good, but sooner or later this question will demand a solution in view of the statistics of immediate and remote results which the sanatoriums are now providing.

Our last comment on Dr. MacNalty's admirable report concerns the examination of contacts, for he was led to make searching inquiry into the system, by the expression of an opinion three years ago in these columns[2] that the examination of child contacts as usually conducted in the dispensary was futile. Since that date statistics for various county areas —e.g., Lancashire, Worcestershire, Devon—and for hospitals such as Brompton, have been published which show that the tuberculosis death-rate amongst contacts is considerably greater than amongst the general population, and we readily admit that the Ministry have made a good case for regarding properly conducted contact examinations as a valuable part of the tuberculosis officer's work. It is not contact examination per se which is futile, it is the lack of perspective so often applied to it which is to be deplored. Such inquiries as are cited in the report have their place and we trust that their scope will be extended, but we should be sorry to see the tuberculosis officer rendered ineffective by sheer weight of numbers, and his clinical interest blunted by routine, all too often of a purely statistical nature. No inconsiderable proportion of juvenile tuberculosis is due to the bovine bacillus and the primary case is to be sought for in the byre rather than in the home. The need at the moment would seem to be a clear statement on the contact problem, what constitutes a "contact," how long does he remain so, on what standard of positive diagnosis shall he be judged—radiogram, or intradermal tuberculin test, or stethoscope—which portion of the contact class is the most important to infants, school-children, or adolescents. These are not quibbles. All cases of tuberculosis are contacts. With the resources at our disposal concentration on the immediately urgent danger points are essential and we must know where they are. Separating out into one group those in whom definite house contact can be established and lumping all the rest with the general population has undoubtedly brought out statistically the importance of home infection, but we are inclined to think there is a danger of obscuring certain other issues such as bovine tuberculosis and factory and workshop infection.

Between the ages of 5 and 45 tuberculosis is still, as Dr. MacNalty puts it, the chief killing disease, and no one can contemplate the curves facing p. 7 without pausing to consider. We have much to congratulate ourselves upon, and the report, considered as an audit, is a document of great merit. But the closing of the account is not yet in sight.

---

[1] A Report on Tuberculosis, including an Examination of the Results of Sanatorium Treatment. By Arthur Salusbury MacNalty, M.A., M.D., F.R.C.P., Senior Medical Officer for Tuberculosis, Ministry of Health. Reports on Public Health and Medical Subjects: No. 64. H. M. Stationery Office. 1932. Pp. 172. 3s.

ST. JOHN'S HOSPITAL, TWICKENHAM.—Recently the Princess Royal opened new wards at St. John's Hospital, Twickenham, and unveiled two memorial tablets. The cost has been £6000, of which only £100 remains to be raised.

few days time. Dr. D'Arcy Hart mentions this in his report, and says that he found the percentage of error to be 5·5 per cent. in a small series. Such anomalies as these make one distrust the test in practice, and it seems that judgment should be reserved until more work has been done on the protein and non-protein fractions of tuberculin. The fact that the tuberculin reaction is not an antigen-antibody phenomenon, but an example of true allergy makes its interpretation difficult.

Drs. Toussaint and MacIntyre do not agree with the conclusion I reached on the question of contacts, and in support of their contention quote cases of miliary and meningeal tuberculosis, and cases of sputum-positive pulmonary tuberculosis in children. The comparability of their cases to mine, and the relationship of mass infection to generalised tuberculosis, is too big a subject to discuss here. In 1000 school-children examined by Barnard, Amberson, Jr., and Loew, in New York, 184 children were found [1] with tuberculous pulmonary lesions demonstrable by X ray; out of these, only eight had a certain history of contact, and a further nine a probable history of contact. This work was quoted in my paper.

I am, Sir, yours faithfully,

ERNEST FLETCHER.

Harley-street, W., March 15th, 1932.

MUCOUS FEVER.

To the Editor of THE LANCET.

SIR,—In your report of what Prof. Storm van Leeuwen said at the discussion on Desensitisation in Allergic Disease (THE LANCET, March 12th, p. 571) reference is made to "Schlamm" fever, "which he translated as *slime* fever." I understood him to say "Schleimfieber," and as the German word "Schleim" means mucus, the English translation would be "mucous fever," which is given in the New Sydenham Society's medical lexicon under *febris mucosa*. However, on looking up "Schleimfieber" in a German *Conversations-Lexikon* of 1886, I find it stated that this "febris mucosa" was a term formerly used for any one of several febrile disorders in which much mucus was secreted, but that "modern medicine" (at that time) had given up the term completely. Evidently "modern medicine" (at the present time) has taken up the term again to signify some particular, not very dangerous, febrile specific infectious disease. Does it exist in England?

I am, Sir, yours faithfully,

London, W., March 12th, 1932. F. PARKES WEBER.

*** According to W. Guttmann's "Medizinische Terminologie" (1923) *Schlamm-fieber* is an epidemic febrile disease, usually of benign course, attended with a measly rash and enlargement of spleen and liver, occurring after prolonged residence on marshy soil or the drinking of bad water. Its exacter ætiology was then unknown.—ED. L.

HÆMORRHAGIC PURPURA FOLLOWING SCARLET FEVER.

To the Editor of THE LANCET.

SIR,—The two cases of hæmorrhagic purpura reported by Dr. Gibson and Dr. Hobson in your issue of March 5th are so curious as to suggest the question whether the hæmorrhages were in fact due to scarlatinal toxin. It would be instructive to know whether hæmolytic streptococci were found and, if so, of what type. Some of the clinical features are more characteristic of a diphtheritic infection. If the infection was a hæmolytic streptococcal one, the cases lend point to the opinion that I have expressed elsewhere that even mild cases of scarlet fever should not have antiscarlatinal serum withheld from them, since even mild cases may have severe toxic complications. The ease with which desensitisation may generally be effected rules out the risk of severe protein shock.

I am, Sir, yours faithfully,

A. H. G. BURTON.

Public Health Offices, Ilford, March 10th, 1932.

INFECTIOUS DISEASE
IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 5TH, 1932.

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 42 (last week 72); scarlet fever, 1482; diphtheria, 886; enteric fever, 36; pneumonia, 2064; puerperal fever, 43; puerperal pyrexia, 106; cerebro-spinal fever, 67; acute poliomyelitis, 3; acute polio-encephalitis, 2; encephalitis lethargica, 12; dysentery, 39; ophthalmia neonatorum, 118. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on March 8th–9th was as follows: Small-pox 101 under treatment, 7 under observation (last week 116 and 2 respectively); scarlet fever, 1344; diphtheria, 1565; enteric fever, 12; measles, 1810; whooping-cough, 392; puerperal fever, 19 (plus 6 babies); encephalitics lethargica, 227; poliomyelitis, 3; "othe diseases," 191. At St. Margaret's Hospital there were 1 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London there was no death from *small-pox or* enteric fever 76 (24) from measles, 8 (2) from scarlet fever, 36 (4 from whooping-cough, 36 (6) from diphtheria, 52 (12 from diarrhœa and enteritis under two years, an 298 (47) from influenza. The figures in parenthese are those for London itself.

The reported deaths from influenza are again on the dow grade. Of the great towns *Leicester* stands highest wi 15 deaths, followed by Sheffield with 14 deaths and Birmin ham with 11 deaths. The total deaths for the year fro influenza so far amount to 2937 compared with 3093 f the corresponding period of 1931. The 1932 record is no better than that of the preceding year. Liverpool report 5 deaths from measles, Willesden and Manchester each Liverpool and Birmingham each reported 4 deaths fro whooping-cough. Diphtheria claimed 4 victims in ea of Hull, Leeds, and Liverpool.

The number of stillbirths notified during the week wa 301 (corresponding to a rate of 45 per 1000 births including 41 in London.

PROVISIONAL DEATH-RATES FOR 1931.

Provisional death-rates per 1,000,000 populatio for England and Wales during the year 1931 are no available as follows:—

	Males.	Females.	Perso
Respiratory tuberculosis	872	622	742
Other tuberculosis	169	140	154
Cancer	1,450	1,516	1,484

The maternal mortality (*provisional*) based deaths primarily classed to puerperal conditions as follows:—

Puerperal sepsis per 1000 live births, 1·66; per 10 total births, 1·59.

Other accidents and diseases of pregnancy and parturiti per 1000 live births, 2·45; per 1000 total births, 2·35.

---

[1] The heading Enteric Fever in this column of the Return h now been amplified so as to make it quite clear that it includ Typhoid and Paratyphoid Fevers.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

VETERINARY SURGEONS BILL.

n the House of Commons on Friday. March 11th. Veterinary Surgeons (Irish Free State Agreement) l, which has already passed through the House of rds, passed through Committee and was read the rd time.

DANGEROUS DRUGS BILL.

n the House of Commons on Monday, March 14th, . OLIVER STANLEY (Under Secretary for Home airs) moved the second reading of the Dangerous ugs Bill which has already passed through the use of Lords. He said the reason for the introduc- n of the Bill was to enable His Majesty's Govern- nt to ratify a Convention agreed to at Geneva t summer. This country had always been to the nt in attempting to regulate the traffic in dangerous ugs. During last summer a largely attended nference was held at Geneva to discuss that estion. The scheme for regulation which was oposed by His Majesty's Government was not cepted by the Conference and they were bound to int out that in their view the scheme which finally rmed the basis of the Convention had a certain fect and would present difficulties in practice. t they acknowledged that the scheme was an vance on the present position, and they therefore came one of the signatories to the Convention. enable this country to ratify that Convention it as necessary to make certain minor amendments the existing law. To a large extent it would be ssible to put the Convention into force under the isting Dangerous Drugs Act, but there were two tain particulars in which it might be necessary to ake an alteration. The first was in regard to rtain derivatives of opium, which were not habit- rming drugs in themselves, but were capable of asily being converted into such. In accordance ith the Convention it was necessary to take power to eal with them. The two drugs which were mainly oncerned were commonly known as codeine and ionin, although they would probably be more familiar o hon. Members under their more scientific name as nethylmorphine and ethylmorphine. The House would realise that those drugs were included together with their respective salts. They were not in themselves drugs medicinally, although they were capable of being converted into such drugs. They were drugs of a useful character which were more and more generally being used as a substitute for more dangerous drugs in medical preparations. Although it was necessary under the Convention to have some control over them they did not want to establish a control of such rigidity as would interfere with their proper purpose and use. They intended therefore under Subsection (3) of Clause 2 of the Bill to extend Part III. of the Dangerous Drugs Act, and to control the process of manufacture of those two drugs. It would be found that when they brought this control into force it would affect neither the retail trade nor the users of these drugs in medical preparations. He felt sure that it would not interfere in any way with legitimate trade in these drugs.

ANTICIPATING NEW DERIVATIVES.

The other alteration that had to be made was in regard to certain new derivatives of opium or the coca leaf which might be invented or discovered in years to come. Up to now they had not been able to deal with new inventions. The scheme as proposed under Clause 2 Subsections (1) and (2) of the Bill was as follows: First of all they would start with a complete ban on the trade or manufacture of any such new derivatives, and if it was found that any new invention of this kind was of medical or scientific value, the ban could be lifted. The next step was that this new-found drug should be submitted to the League of Nations for their report as to whether it was a drug of addiction, or a drug which was capable of being so converted. If it was found that this new drug had no medical or scientific value, then the ban would not be lifted. If it was found that the drug was of medical or scientific value then the ban would be lifted. If the League of Nations found that it was a drug of addiction then they could bring into operation Part III. of the principal Act. If they found that it was not a drug of addiction, but was capable of being converted into one, then they were entitled to use the same procedure as he had already detailed in the case of the other two drugs. Finally, this Bill was to be brought into operation by Order in Council. The necessity for that was that the Convention would not come into force until it was ratified by 25 of the signatories, including at least four of the main manufacturing countries, and it was necessary therefore to retain a discretion as to when it should come into force.

Mr. RHYS DAVIES said that as far as the opposition were concerned they gave their blessing to the Bill. It was a very necessary measure. Whenever the Government took an international line on any subject they were inclined to support them.

Sir WILFRID SUGDEN asked if the Bill had the assent of the veterinary surgeons, the British Medical Association, or the Society of Pharmacists of Great Britain and Ireland, the three bodies mainly interested in what was being done.

Mr. C. WILLIAMS warned the Government that although he accepted the Bill as a whole quite readily, when they reached the Committee stage he might wish to omit one or two of the words in Subsection (*g*) of Clause 1.

Mr. STANLEY said that the Convention which the Bill was intended to ratify had been laid before Parliament and formed the subject of a White Paper. In view of the fact that the Government had received no representations against it he thought they could conclude that the Bill was agreed to.

The Bill was read a second time and committed to a Committee of the whole House.

KETTERING GAS BILL.

On Monday, March 14th, the House of Commons debated the Kettering Gas Bill on second reading. The Bill, which is a private measure, raises a principle of some importance both locally and nationally. The Preamble states that the Kettering Urban District Council is authorised to supply electricity for public and private purposes, and is also developing certain housing estates within its area. It adds that the tenants of the houses on one of the estates are precluded from obtaining a supply of gas for any purposes other than certain specified purposes, and that the tenants on the remaining estates have been prevented from obtaining a supply of gas for any purpose. The object of the Bill is to prevent the Council imposing restrictions with respect to the form of light, heat, power, or energy supplied to any property for the time being belonging or leased to them.

In the course of the debate it was strongly urged by several Members that the citizens should have the

---

a proficient French and German scholar. He was personally known to a very large number of the medical profession as a publisher and one of the proprietors of the Medical Directory. The firm started in 1825, and was concerned in several ways with the publication of THE LANCET in early days. It is now represented by Mr. A. W. Churchill, Mr. Theodore Churchill's cousin.

OBITUARY

THOMAS GEORGE STYAN, M.D. Camb.

THE death took place on March 13th at his residence in Sevenoaks of Dr. Thomas Styan, who practised before retirement at Ramsgate for some 40 years, and was one of the best known practitioners in the Isle of Thanet.

Thomas George Styan was educated at Uppingham and Trinity College, Cambridge, where he graduated in Arts in 1878. He proceeded to St. Bartholomew's Hospital, took the M.B. Cambridge in 1885, and held the appointment of house physician at the hospital. He later filled an appointment at the Salop Infirmary, took the M.D. degree in 1887, and in the following year succeeded to the practice in Ramsgate of Dr. Samuel Woodman. He made an immediate mark as a careful practitioner and a competent surgeon. He was appointed surgeon to the Ramsgate and St. Lawrence Royal Dispensary, and in 1889 to the Ramsgate General Hospital and Seamen's Infirmary; was medical officer of health to the borough and port of Ramsgate, and school medical officer, Ramsgate Education Committee.

During the war Dr. Styan gave valuable service. He was surgeon to the Kent 2 V.A.D. Auxiliary Military Hospital at Ramsgate from Oct. 10th, 1914. In the conversion of Nether Court Manor House into a hospital he advised as to providing extra wards and an operating theatre, and in general superintended the organisation. Up to Oct. 10th, 1917, 2073 patients passed through this hospital, the majority of which were acute surgical cases coming direct from France and requiring operation. This hospital was closed when the town was subjected to very severe bombing. Until the termination of the war great demands were made upon Dr. Styan's services by the local general hospital, which also received many military patients as well as victims from the constant air-raids. His name was brought before those in authority several times, because of this thorough and valuable work, while for his services in connexion with Belgian refugees and wounded soldiers he was decorated by the King of the Belgians and made an officer of the Order of St. John of Jerusalem.

Dr. Styan, who was 75 years of age, had been both at Uppingham and Cambridge a fine football player, and in 1878 was captain of the University association team.

HERBERT WILLIAM CUNINGHAM, M.D.R.U.I.

Dr. H. W. Cuningham, who died suddenly in his consulting room on Feb. 25th, was in his sixty-fourth year. He was educated at the Academical Institution, Londonderry, and took his medical course at the Queen's University of Belfast, graduating with distinction in the Royal University of Ireland in 1892. After acting as house physician in the Royal Hospital, Belfast, and obtaining some experience in England, he commenced practice in his native city of Londonderry, and took his M.D. in 1895. He was appointed medical officer to Londonderry No. 1 and Upper Liberties Dispensary District, a post he occupied for 33 years, and from which he was on the point of retiring. For 20 years he was honorary visiting physician to the Derry City and County Infirmary. He also acted as medical visitor in lunacy for the Lord Chief Justice of Northern Ireland. He was president of the Ulster branch of the British Medical Association in 1924, when he delivered a thoughtful and literary address on Nerve Exhaustion. During the war he carried out the duties of civil surgeon at the military barracks. He took a part in the social life of the city, being a governor of Foyle College and of the Londonderry High School. He was fond of music, and was one of the original founders of the Derry Philharmonic Society. The colleague, who sends us these details, writes of Dr. Cuningham's quiet dignity and charm of manner, his strict sense of honour, his warm heart and generous disposition, his professional skill and ready sympathy which made him beloved as a physician, not only in Londonderry, but among his colleagues throughout Ulster.

THE LATE LIEUT.-COL. J. H. REYNOLDS, V.C

To the brief note on the adventurous career o Colonel Reynolds in our last issue Mr. W. G. Spencer, consulting surgeon to the Westminster Hospital, adds the following reminiscences: "Whilst Col Reynolds was in charge of the Pimlico Clothing Department he was accustomed to send work women to me at the hospital, and later he came t me about his health, the last time at the beginning of 1929. Then a growth for which a grave operation would otherwise have been called for disappeared i about ten days under radium. Col. Reynolds wa thus able to walk at the head of the V.C.'s at th thanksgiving ceremony, and to be present at th dinner in the House of Lords. Our conversation often returned to Rorke's Drift, and from notes jotted down I pick out a few of his reminiscenc which I have not noticed in the general story.

"There were 36 patients in hospital, most in di ferent stages of typhoid fever. N [illegible] h been made for the defence of the [illegible] was the senior officer, having been already six yea in South Africa; Bromhead and Chard were you subalterns, just out from England; Dalton was Army non-com, who had rejoined, and had h experience in the methods of defence employed the Boers, and when fugitives from Isandhlwa reached Rorke's Drift it was first proposed to evacu the station, but Reynolds declared that to be imp sible. Even if the convoy could cross the river t ascent of the opposite bank was so long and ste that the Zulus would certainly catch it up. It w Dalton who arranged the defence with mealie ba When the Zulus came into view there appea horsemen in scarlet, and the cry was that the cava were returning, but Reynolds pointed out that t riders were not rising in their saddles, but sat t horses as did natives. Coming nearer, the Zulu in drew up and ceremoniously took snuff, heraldi a charge to the uttermost. A few Zulus got i the garden and into the hospital before two patie in bed could be got within the lager; a third l his head, took a wrong turning, and was kill The remaining 33 cases were saved."

MR. J. THEODORE CHURCHILL.—Mr. J. T. Church senior partner in the well-known firm of Mess J. and A. Churchill, died suddenly at Matlock March 11th. Mr. Churchill received part of education in Berlin and part in Paris, and was th

He said the reason for the introduc- n of the Bill was to enable His Majesty's Govern- nt to ratify a Convention agreed to at Geneva t summer. This country had always been to the nt in attempting to regulate the traffic in dangerous gs. During last summer a largely attended ference was held at Geneva to discuss that stion. The scheme for regulation which was posed by His Majesty's Government was not pted by the Conference and they were bound to int out that in their view the scheme which finally med the basis of the Convention had a certain fect and would present difficulties in practice. t they acknowledged that the scheme was an vance on the present position. and they therefore came one of the signatories to the Convention. enable this country to ratify that Convention it s necessary to make certain minor amendments the existing law. To a large extent it would be ssible to put the Convention into force under the isting Dangerous Drugs Act. but there were two ain particulars in which it might be necessary to ake an alteration. The first was in regard to tain derivatives of opium. which were not habit- rming drugs in themselves. but were capable of ily being converted into such. In accordance ith the Convention it was necessary to take power to eal with them. The two drugs which were mainly oncerned were commonly known as codeine and onin. although they would probably be more familiar o hon. Members under their more scientific name as thylmorphine and ethylmorphine. The House ould realise that those drugs were included together ith their respective salts. They were not in them- elves drugs medicinally. although they were capable f being converted into such drugs. They were rugs of a useful character which were more and more nerally being used as a substitute for more dangerous rugs in medical preparations. Although it was cessary under the Convention to have some control ver them they did not want to establish a control f such rigidity as would interfere with their proper urpose and use. They intended therefore under ubsection (3) of Clause 2 of the Bill to extend Part III. f the Dangerous Drugs Act, and to control the rocess of manufacture of those two drugs. It would found that when they brought this control into force it would affect neither the retail trade nor the rs of these drugs in medical preparations. He lt sure that it would not interfere in any way with gitimate trade in these drugs.

ANTICIPATING NEW DERIVATIVES.

The other alteration that had to be made was in regard to certain new derivatives of opium or the coca leaf which might be invented or discovered in years to come. Up to now they had not been able to deal with new inventions. The scheme as proposed under Clause 2 Subsections (1) and (2) of the Bill was as follows: First of all they would start with a complete ban on the trade or manufacture of any such new derivatives. and if it was found that any new invention of this kind was of medical or scientific value. the ban could be lifted. The next step was that this new-found drug should be submitted to the League of Nations for their report as to whether it was a drug of addiction. or a drug which was capable of being so converted. If it was found that this new drug had no medical or scientific value. then the ban would not be lifted. If it was found that the drug was of medical or scientific value then the ban would be lifted. If the League of Nations found that it was a drug of addiction then they could bring into operation Part III. of the principal Act. If they found that it was not a drug of addiction. but was capable of being converted into one. then they were entitled to use the same procedure as he had already detailed in the case of the other two drugs. Finally, this Bill was to be brought into operation by Order in Council. The necessity for that was that the Convention would not come into force until it was ratified by 25 of the signatories. including at least four of the main manufacturing countries. and it was necessary therefore to retain a discretion as to when it should come into force.

Mr. RHYS DAVIES said that as far as the opposition were concerned they gave their blessing to the Bill. It was a very necessary measure. Whenever the Government took an international line on any subject they were inclined to support them.

Sir WILFRID SUGDEN asked if the Bill had the assent of the veterinary surgeons. the British Medical Association, or the Society of Pharmacists of Great Britain and Ireland. the three bodies mainly interested in what was being done.

Mr. C. WILLIAMS warned the Government that although he accepted the Bill as a whole quite readily. when they reached the Committee stage he might wish to omit one or two of the words in Subsection (*g*) of Clause 1.

Mr. STANLEY said that the Convention which the Bill was intended to ratify had been laid before Parliament and formed the subject of a White Paper. In view of the fact that the Government had received no representations against it he thought they could conclude that the Bill was agreed to.

The Bill was read a second time and committed to a Committee of the whole House.

KETTERING GAS BILL.

On Monday. March 14th, the House of Commons debated the Kettering Gas Bill on second reading. The Bill. which is a private measure. raises a principle of some importance both locally and nationally. The Preamble states that the Kettering Urban District Council is authorised to supply electricity for public and private purposes, and is also developing certain housing estates within its area. It adds that the tenants of the houses on one of the estates are precluded from obtaining a supply of gas for any purposes other than certain specified purposes. and that the tenants on the remaining estates have been prevented from obtaining a supply of gas for any purpose. The object of the Bill is to prevent the Council imposing restrictions with respect to the form of light, heat, power, or energy supplied to any property for the time being belonging or leased to them.

In the course of the debate it was strongly urged by several Members that the citizens should have the

a proficient French and German scholar. He was rsonally known to a very large number of the dical profession as a publisher and one of the proprictors of the Medical Directory. The firm arted in 1825, and was concerned in several ways with the publication of THE LANCET in early days. It is now represented by Mr. A. W. Churchill, Mr. Theodore Churchill's cousin.

OBITUARY

THOMAS GEORGE STYAN, M.D. Camb.

The death took place on March 13th at his residence in Sevenoaks of Dr. Thomas Styan, who practised before retirement at Ramsgate for some 40 years, and was one of the best known practitioners in the Isle of Thanet.

Thomas George Styan was educated at Uppingham and Trinity College, Cambridge, where he graduated in Arts in 1878. He proceeded to St. Bartholomew's Hospital, took the M.B. Cambridge in 1885, and held the appointment of house physician at the hospital. He later filled an appointment at the Salop Infirmary, took the M.D. degree in 1887, and in the following year succeeded to the practice in Ramsgate of Dr. Samuel Woodman. He made an immediate mark as a careful practitioner and a competent surgeon. He was appointed surgeon to the Ramsgate and St. Lawrence Royal Dispensary, and in 1889 to the Ramsgate General Hospital and Seamen's Infirmary; was medical officer of health to the borough and port of Ramsgate, and school medical officer, Ramsgate Education Committee.

During the war Dr. Styan gave valuable service. He was surgeon to the Kent 2 V.A.D. Auxiliary Military Hospital at Ramsgate from Oct. 10th, 1914. In the conversion of Nether Court Manor House into a hospital he advised as to providing extra wards and an operating theatre, and in general superintended the organisation. Up to Oct. 10th, 1917, 2073 patients passed through this hospital, the majority of which were acute surgical cases coming direct from France and requiring operation. This hospital was closed when the town was subjected to very severe bombing. Until the termination of the war great demands were made upon Dr. Styan's services by the local general hospital, which also received many military patients as well as victims from the constant air-raids. His name was brought before those in authority several times, because of this thorough and valuable work, while for his services in connexion with Belgian refugees and wounded soldiers he was decorated by the King of the Belgians and made an officer of the Order of St. John of Jerusalem.

Dr. Styan, who was 75 years of age, had been both at Uppingham and Cambridge a fine football player, and in 1878 was captain of the University association team.

HERBERT WILLIAM CUNINGHAM, M.D.R.U.I.

Dr. H. W. Cuningham, who died suddenly in his consulting room on Feb. 25th, was in his sixty-fourth year. He was educated at the Academical Institution, Londonderry, and took his medical course at the Queen's University of Belfast, graduating with distinction in the Royal University of Ireland in 1892. After acting as house physician in the Royal Hospital, Belfast, and obtaining some experience in England, he commenced practice in his native city of Londonderry, and took his M.D. in 1895. He was appointed medical officer to Londonderry No. 1 and Upper Liberties Dispensary District, a post he occupied for 33 years, and from which he was on the point of retiring. For 20 years he was honorary visiting physician to the Derry City and County Infirmary. He also acted as medical visitor in lunacy for the Lord Chief Justice of Northern Ireland. He was president of the Ulster branch of the British Medical Association in 1924, when he delivered a thoughtful and literary address on Nerve Exhaus tion. During the war he carried out the duties of civil surgeon at the military barracks. He took a part in the social life of the city, being a governor o Foyle College and of the Londonderry High School He was fond of music, and was one of the origina founders of the Derry Philharmonic Society. Th colleague, who sends us these details, writes of D Cuningham's quiet dignity and charm of manne his strict sense of honour, his warm heart and generou disposition, his professional skill and ready sympatl which made him beloved as a physician, not only Londonderry, but among his colleagues througho Ulster.

THE LATE LIEUT.-COL. J. H. REYNOLDS, V.

To the brief note on the adventurous career Colonel Reynolds in our last issue Mr. W. G. Spenc consulting surgeon to the Westminster Hospit adds the following reminiscences: "Whilst C Reynolds was in charge of the Pimlico Clothi Department he was accustomed to send wo women to me at the hospital, and later he came me about his health, the last time at the beginni of 1929. Then a growth for which a grave operati would otherwise have been called for disappeared about ten days under radium. Col. Reynolds thus able to walk at the head of the V.C.'s at thanksgiving ceremony, and to be present at dinner in the House of Lords. Our conversati often returned to Rorke's Drift, and from note jotted down I pick out a few of his reminiscen which I have not noticed in the general story.

"There were 36 patients in hospital, most in ferent stages of typhoid fever. No preparations been made for the defence of the station. Reyn was the senior officer, having been already six y in South Africa; Bromhead and Chard were yo subalterns, just out from England; Dalton was Army non-com, who had rejoined, and had experience in the methods of defence employed the Boers, and when fugitives from Isandhlw reached Rorke's Drift it was first proposed to evacu the station, but Reynolds declared that to be im sible. Even if the convoy could cross the river ascent of the opposite bank was so long and s that the Zulus would certainly catch it up. It Dalton who arranged the defence with mealie b When the Zulus came into view there appe horsemen in scarlet, and the cry was that the cav were returning, but Reynolds pointed out that riders were not rising in their saddles, but sat horses as did natives. Coming nearer, the Zulu drew up and ceremoniously took snuff, heral *a charge to the uttermost.* A few Zulus got the garden and into the hospital before two pati in bed could be got within the lager; a third his head, took a wrong turning, and was ki The remaining 33 cases were saved."

MR. J. THEODORE CHURCHILL.—Mr. J. T. Churc senior partner in the well-known firm of Me J. and A. Churchill, died suddenly at Matlock March 11th. Mr. Churchill received part of education in Berlin and part in Paris, and was

(*Continued at foot of opposite page.*)

Water-supplies in Rural Areas.

. Rosbotham asked the Minister of Health if his ition had been drawn to the fact that many rural hes were in need of public water-supplies; and if ould consider taking steps as early as possible to make al grants to rural district councils to enable them to dy the conditions under which many of the inhabitants ined their daily supplies.—Sir E. Hilton Young ed: I am aware of the inadequacy of the water-supply me rural parishes. Conditions generally have improved cent years, loans amounting to £2,000,000 in respect ral schems having been sanctioned by my department ng the last three years. As regards the second part of question, I cannot hold out any hope of special assistance g available from the Exchequer, but I may point out it is open to county councils to contribute to the cost hemes.

Vaccination and Encephalitis.

r Groves asked the Minister of Health whether any ges had been made in the methods of manufacturing ine lymph in the Government lymph establishment, a view to the prevention of the risk of post-vaccinal phalitis; and whether the changes, if any, included the ndonment of the use of rabbits for the purpose of ngthening the lymph supplies.—Sir E. Hilton Young ied: This question has been fully considered, and no change has been made or is contemplated I am advised there is no evidence to suggest that the use of rabbits the preparation of lymph has any influence on the rrence of post-vaccinal encephalitis.

eague of Nations and Statistics of Small-pox.

r Groves asked the Minister of Health whether he ld consider the advisability of making representations he League of Nations health committee in regard to the r in which statistics of small-pox cases were set forth their periodical Reports, in view of the fact that no rimination was made in the Reports between the mild l almost non fatal variety of small-pox, known as alastrim, ich had been recently prevalent in England, and the ere or classical type which was prevalent for the most part where—Sir E. Hilton Young replied: Distinctions ween the two varieties of small-pox appear in the latest these Reports which deal with epidemics of this disease e Reports are issued solely on the responsibility of the alth section of the Secretariat of the League of Nations l specifically stated in each Report that the responsibility the Health Committee of the League is not involved.

Dead Bodies Recovered from the Thames.

Mr. Cocks asked the Home Secretary how many dead dies were taken from the Thames for the year ended h 29th, 1932; and what were the verdicts recorded at inquests.—Sir Herbert Samuel replied: I can only ve figures for the City of London and Metropolitan police strict, as follows. The number of bodies was 158 and the rdicts at the inquests were: found drowned and open rdict, 56; suicide, 46; accident or misadventure, 39; illborn or want of attention at birth, 15; murder (newly-orn), 1; cause not known, 1.

Murder Statistics for England and Wales.

Mr Cocks asked the Home Secretary if he would state ow many murders were known to the police in England and ales during the years 1930 and 1931, respectively; in ow many cases the supposed murderer committed suicide; ow many persons were proceeded against for murder; ow many of such persons were found to be insane before al or on arraignment, or guilty but insane; how many of ch persons were convicted of murder excluding those found ilty but insane; and how many of those convicted of rder were subsequently executed.—Sir Herbert Samuel plied: The full details desired are not yet available for 931. In 1930, 108 murders were known to the police, volving 119 victims, of whom 22 were newly-born infants ose bodies were found in such circumstances as to afford o clues enabling arrests to be made Thirty-six suspects mmitted suicide: 41 were proceeded against: 17 were und to be insane: 14 were convicted and sentenced to ath, the sentence being executed on six of them

MONDAY, MARCH 14TH.

Milk-supply and Public Health.

Captain Elliston asked the Minister of Agriculture ther, in view of the connexion of the milk supply with various aspects of health and the prevention of disease, ntation would be given to the public health interests the commission for the reorganisation of the milk dustry—Sir John Gilmour replied: I regret I cannot rtake to give representation on the commission to any particular interest, but I will, however, bear my hon. friend's suggestion in mind.

Remedies for Pulmonary Phthisis.

Mr. Mander asked the Minister of Health whether he was aware of the cures effected in cases of pulmonary phthisis by the British remedy Umckaloabo; and whether he would give instructions for this fact to be officially brought to the notice of medical officers in official appointments concerned with this disease—Sir E Hilton Young replied: The evidence available in regard to the efficacy of this preparation has been carefully considered on several occasions I am advised that the claims made on its behalf in regard to tuberculosis do not appear to differ in character or degree from those made for many other so called ' remedies " which have been advertised from time to time and afterwards found to be valueless. The answer to the second part of the question is in the negative.

Sickness among Women Workers.

Mr. Louis Smith asked the Minister of Health whether his attention had been called to the increase of sickness among women workers coming under the national health insurance scheme, and especially married women; and whether he could give any accepted explanation of such increase.—Sir E. Hilton Young replied: I am aware of the increase that has taken place in the claims of insured women workers, and particularly married women, to sickness and disablement benefit, as compared with the experience of some years ago. It is not possible to give a specific explanation of this increase, which is believed to be the combined result of a number of causes acting together. The whole subject of women's insurance is at present engaging my attention.

Fatal Railway and Road Accidents.

Mr. Somervell asked the Home Secretary how many persons had been killed in railway accidents and road accidents, respectively, in the last five years—Sir H. Samuel replied: The number of persons killed in Great Britain in railway and road accidents respectively during the years since 1926 were as follows.—

	1926.	*1927.*	*1928.*	*1929.*	*1930.*	*Total.*
Railway	374	435	160	417	380	2,066
Road	4886	5329	6138	6696	7305	30,354

For 1931 the figures of railway accidents are not yet available; the number of road accidents was 6690.

TUESDAY, MARCH 15TH.

Provision of Meals for School-children.

Mr Joel asked the President of the Board of Education whether the estimate for special services in connexion with elementary education outlay showed any increase in the provision of meals for children: and whether he was satisfied that this requirement was adequately met—Mr. Ramsbotham (Parliamentary Secretary to the Board of Education) replied: In the Board's estimates for 1932 allowance is made for increased expenditure by local education authorities on the provision of meals to the extent of £20,000, as shown on page 12 of the Estimates Memorandum (Cmd 4031) It is not possible to forecast the actual expenditure to be incurred on this service, but my right hon. friend is satisfied that, so far as can at present be ascertained, the estimate is adequate for any probable requirements.

Medical and Dental Officers in the Navy.

Mr. Price asked the First Lord of the Admiralty whether the number of medical and dental officers was up to the establishment, as no provision was made for examinations for entry in the Estimates for 1932—Lord Stanley (Parliamentary Secretary to the Admiralty) replied: The establishment of naval medical officers is not complete, there being a deficiency of approximately 60. The entrance examination is at present in abeyance, and entries are being made for short service by selection after interview. The number of dental officers is one short of establishment. When the number of vacancies does not justify the holding of a competitive examination, entries are made by selection after interview in the same manner as for the entry of medical officers for short service.

A "LEWIS CARROLL WARD."—It is proposed to endow a ward for children at St Mary's Hospital, W.2, as a tribute to the author of "Alice in Wonderland" at a minimum cost of £10,000 The scheme is supported by the Prime Minister, Mr Stanley Baldwin, Mrs Hargreaves (the original "Alice"), Sir J. M. Barrie, and other distinguished persons right to choose whether they would have gas or electricity in their houses.

Dr. HOWITT said he regarded it as entirely wrong to grant to any council the power to force either gas or electricity upon its tenants, and not to allow them the choice of having either or both. There were in this country at present too many laws restricting the liberty of the individual. If this Bill was not passed the poorer tenants in these council houses at Kettering would not be able to afford electric light, and would have to use candles and oil lamps. He spoke as a doctor who had spent many years of his life in Lambeth, working under conditions such as that, and it was very difficult indeed for a medical man to attend adequately to any patient in distress under such conditions. He had been told that in certain council houses in this country doctors who had been called to confinement cases had to carry on their work by the spluttering light of a candle. That was a monstrous thing to happen in these days. He urged the House to give the Bill a second reading.

Mr. ERNEST BROWN (Parliamentary Secretary to the Ministry of Health) said that the Minister of Health had given this matter very careful consideration, and it was his clear opinion that this Bill should go to a Committee of the House where the issues could be thrashed out.

The Bill was read a second time.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 9TH.

Increase in Mental Deficiency.

Sir JOHN BIRCHALL asked the Minister of Health whether he had considered the resolution sent to him by the Leeds City Council in reference to the increase in mentally deficient persons and advocating a measure to prevent the procreation of children by mentally deficient persons; and whether he proposed to take any steps in the direction indicated.—Mr. E. BROWN (Parliamentary Secretary to the Ministry of Health) replied: Yes, Sir. As indicated in my reply to a question on Feb. 15th, my right hon. friend is arranging for certain preliminary investigations as a first step towards a general inquiry into this problem.

Tin Foil Wrapping.

Mr. THORNE asked the Minister of Health the number of poisoning cases which had been proved to be attributable to foodstuffs wrapped in tin or lead foil; and whether he would consider the advisability of issuing an order for the immediate wrapping of foodstuffs to be either grease-proof or cellophane.—Mr. ERNEST BROWN replied: Apart from one unverified case in which poisoning was suggested, my right hon. friend has no information that wrappers of tin or lead foil have been the cause of food poisoning. In these circumstances, he would not be justified in making such an order as is suggested.

Tuberculosis in Glasgow Area.

Mr. MCGOVERN asked the Secretary of State for Scotland the number of persons from the Glasgow area who were at present certified as suffering from tuberculosis; the number in institutions; the names of the institutions concerned; and the ages of the persons.—Sir ARCHIBALD SINCLAIR replied: The number of persons in Glasgow who were known to be suffering from tuberculosis on the 3rd instant was 9675. The number of Glasgow tuberculosis patients in institutions on that date was 1714 and the names of the institutions in which these patients were resident are as follows: Ruchill Hospital, Knightswood Hospital, Robroyston Hospital, Bellefield Sanatorium, Mearnskirk Hospital, Darnley Hospital, Ochil Hills Sanatorium, Bridge of Weir Sanatorium, Dunblane Sanatorium, Lanfine Homes, Stobhill Hospital, Barnhill Hospital, Eastern District Hospital, Oakbank Hospital, Merryflats Hospital, Hairmyres Sanatorium, and Strathblane Children's Hospital. The patients in question are of all ages, and to classify them according to age would involve an amount of labour out of proportion to the value of the result.

Hypodermic Syringes for Panel Patients.

Mr. LOGAN asked the Minister of Health if he was prepared to include in the second schedule to the National Health Insurance Consolidated Regulations hypodermic syringes and needles, so that insured patients might use them for asthma self-treatment, when prescribed.—Sir E. HILTON YOUNG replied: As the result of a recent discussion of this matter by my department with representatives of doctors in insurance practice, I am not satisfied that there are any sufficient reasons for making these appliances available as part of medical benefit.

THURSDAY, MARCH 10TH.

Experiments on a Monkey.

Mr. HOPKIN MORRIS asked the Home Secretary if his attention had been called to experiments performed upon a monkey, denominated for the purposes of the experiments monkey 420, involving severe and enduring pain; and whether in this case the animal was forthwith painlessly destroyed.—Sir HERBERT SAMUEL replied: I presume that the hon. Member is referring to the experiments performed in the course of the investigation into an outbreak of rabies in Trinidad an account of which was published in THE LANCET of Sept. 19th last. I am advised that the symptoms recorded in the report of the experiments were mental in character due to the injections, and that there is no reason to suppose that the animal was suffering severe pain which was likely to endure.

Mr. MORRIS: Is the right hon. gentleman aware that it the article describing this experiment it is stated that th animal was kept alive for a period of ten days?

Sir H. SAMUEL: No, Sir. I was unaware that it was ten days, but that does not affect the answer I have given.

Scientific Analysis and Criminal Investigation.

Mr. CROSS asked the Home Secretary whether in view o the high cost of fees paid to analysts and others by th metropolitan police, he would give instructions for al examinations of garments and other specimens to be carrie out by the scientific branch of the Criminal Investigatio Department at Scotland Yard in all cases which could b dealt with by means of ordinary scientific apparatus.—Sir HERBERT SAMUEL replied: The total cost of such fees i any one year is not high, the average for the last three yea being less than £100 a year. Where expert evidence o scientific matters is in question, it is better that it shoul be given by independent witnesses free upon occasion t give evidence either for a prosecution or for a defence at not regularly employed to give evidence for the police onl

Sexual Offences against Young Children.

Viscountess ASTOR asked the Home Secretary wheth he was aware that sexual offences against children und 16 were increasing; that the five-year average for indece assaults against them was the highest recorded for ov 30 years; and what steps he proposed to take to che these offences.—Sir HERBERT SAMUEL replied: The figu of offences of defiling girls under 13 show a decrease, l those respecting girls from 13 to 16 an increase. There reason to believe that the statistics are affected by a grea readiness on the part of relatives and friends to report offen to the police instead of concealing them. I would add th the number of persons proceeded against also shows appreciable increase.

Viscountess ASTOR: Does not the right hon. gentlem think that it would be wise to increase the number of women police, because many parents will report to won when they will not report to men, and is he aware tha committee set up to look into sexual offences recommen that we should have more women police?

Sir H. SAMUEL: It is possible, and indeed probable t offences are more readily reported in some cases to won police, but a very large increase in the number of won police might not succeed in stopping the actual offen themselves.

Mr. BRIANT asked the Home Secretary if he could giv statement showing the number of complaints made to police during each of the years 1926–31 of sexual offen against young persons; and the number of persons char with these offences during the same period.—Sir HERB SAMUEL replied: The following are the numbers of offences known to police and (B) persons proceeded agai in Courts of Summary Jurisdiction for certain sexual offen during the years 1926 to 1930.

ADDRESSES AND ORIGINAL ARTICLES

IE PATHOLOGY AND TREATMENT OF ANÆMIA.

: L. J. WITTS, M.D. MANCH., F.R.C.P. LOND.,
TANT PHYSICIAN TO GUY'S HOSPITAL; WILL EDMONDS CLINICAL RESEARCH FELLOW.

LECTURE III.*

(*Concluded from p. 605.*)

The Hæmolytic Anæmia of Pregnancy.

opening a discussion of the hæmolytic anæmia regnancy one enters a field of the greatest usion and controversy. Few diseases have a more ous and less critical literature and there is need for : coöperation between obstetrician and hæmagist in its study. A mild anæmia is physiological ag and after gestation and all forms of anæmia aggravated at this time. There seems to be no . of anæmia, however grave, in which pregnancy not been recorded. The chronic microcytic nia. so common in women in temperate zones. the macrocytic anæmia of the tropics, both reach ' most extreme severity in the pregnant woman. :tion at labour may allow the passage into the d stream of hæmolytic organisms which rapidly ce a profound anæmia. Nevertheless for over a ury it has been realised that there is a severe nia of pregnancy which affects women who were erfect health before conception, which occurs he absence of any sign of infection, and which ppears completely if the patient survives her nancy and puerperium.

is a rare disease. Beckmann (1921) found only :ases in 60,000 births in Vienna and two of these cases certainly were not hæmolytic anæmia. stigation of the records of over 4000 labours ucted at Queen Charlotte's Maternity Hospital 926 and 1927 failed to disclose a single case.[22] ; one case has been recorded at Guy's Hospital ne last ten years. On the other hand many cases t be missed, as is shown by the large number of s which individuals interested in the disease have onally studied, and by the appearance of cases district or hospital coincident with the development of an interest in hæmatology. The disease urs in primiparæ and multiparæ, and at all periods he reproductive life. Analysis of the age and parity women affected shows little difference from the ings in a group of normal pregnant women or in er accidents and complications of childbirth. miparæ are more susceptible than multiparæ, the difference is not great. The disease has relationship with the toxæmia of pregnancy or h puerperal infection. It is true that œdema and noderate albuminuria are present in many of these emic women, and that they are exceptionally ne to intercurrent infection, but there is no more imate connexion than this. Nevertheless the nical resemblance may be great, and as hæmolytic emia is rare, it is only natural that it should often ve been confused with these much more common ladies of pregnancy, toxæmia, and infection.

CHARACTERISTICS OF THE ANÆMIA.

By the time the patients seek medical advice they : already profoundly anæmic. The early symptoms of the disease are overlooked or regarded as the ordinary discomforts of pregnancy. The anæmia increases fast as the disease approaches its climax. Extreme dyspnœa, œdema, syncopal attacks, transient blindness or paralysis, causeless hæmorrhage, uncontrollable vomiting or diarrhœa, one or more of the symptoms at last makes the patient aware that this is no normal pregnancy. The attendants are alarmed by the death-like pallor and examination of the blood reveals a severe megalocytic anæmia. The temperature is raised throughout the period of anæmia, falling to normal when improvement begins, whether spontaneously or as the result of treatment. The pallor has an icteric tinge but overt jaundice is most unusual. Urobilin is present in the urine and the indirect van den Bergh reaction is positive. Filo found that the excretion of bilirubin derivatives in the urine and fæces was increased up to three times the normal. In one case in which he made a series of estimations before and after confinement, the bilirubin excretion sank rapidly from three times the normal to subnormal at a time when the red cells were still falling; with improvement in the blood picture the bilirubin excretion was finally stabilised at the normal level. The spleen is palpable in little more than a third of all cases. In size it varies from being only just palpable to extending three or four inches below the ribs. It vanishes beneath the costal margin on repair of the anæmia. There is no evidence that enlargement of the spleen can be taken as a favourable prognostic sign, as has been suggested.[2] The liver is enlarged in a smaller fraction of cases, usually in association with the spleen but sometimes alone. Earlier writers regarded syphilis as an important ætiological factor, but its importance is not substantiated either by the clinical and post-mortem findings or by Wassermann's reaction. In 43 cases where this reaction was recorded, 35 were negative, 2 doubtful, and only 6 positive. Nor is there any instance in which antisyphilitic treatment has favourably influenced the course of the disease.

The anæmia is of the plastic type with signs of rapid regeneration of red cells, polychromasia, punctate basophilia, and nucleated red cells. The regenerative phenomena reach a climax with the remission, complete or incomplete, which occurs after labour, but they are also present before. Absence of signs of regeneration, especially after confinement, is a finding of ill omen. The fragility of the red cells seems usually to be increased as long as the patient is pregnant (Table II.). After confinement the fragility returns to normal even though the anæmia persists. The white cells are normal or increased by a polynuclear leucocytosis. A few myelocytes are found in practically every case, and they may produce a leukanæmic blood picture. Platelets are always diminished when the anæmia is severe and they may be practically absent. They rapidly return to normal values when the anæmia remits. Purpura and external hæmorrhage occur in about one-third of the cases, and there may be bleeding from the nose, the gums, or the gastro-intestinal tract. There may be vaginal hæmorrhage before the baby is born, but curiously enough the blood loss at confinement is less than normal.

Reticulocytosis before confinement was noted by Minot and by Peterson, while Evans's patient had 40 per cent. about the tenth day of the puerperium before any treatment had been given. Large numbers of megaloblasts were noted before labour by Jungmann and by Brault.

LECTURE III.*

(*Concluded from p. 605.*)

The Hæmolytic Anæmia of Pregnancy.

N opening a discussion of the hæmolytic anæmia pregnancy one enters a field of the greatest fusion and controversy. Few diseases have a more dous and less critical literature and there is need for re coöperation between obstetrician and hæmagist in its study. A mild anæmia is physiological ing and after gestation and all forms of anæmia aggravated at this time. There seems to be no m of anæmia, however grave, in which pregnancy not been recorded. The chronic microcytic emia, so common in women in temperate zones. l the macrocytic anæmia of the tropics, both reach ir most extreme severity in the pregnant woman. ection at labour may allow the passage into the od stream of hæmolytic organisms which rapidly uce a profound anæmia. Nevertheless for over a tury it has been realised that there is a severe æmia of pregnancy which affects women who were perfect health before conception, which occurs the absence of any sign of infection, and which appears completely if the patient survives her gnancy and puerperium.

It is a rare disease. Beckmann (1921) found only cases in 60,000 births in Vienna and two of these cases certainly were not hæmolytic anæmia. vestigation of the records of over 4000 labours nducted at Queen Charlotte's Maternity Hospital 1926 and 1927 failed to disclose a single case.[22] nly one case has been recorded at Guy's Hospital the last ten years. On the other hand many cases ust be missed, as is shown by the large number of ses which individuals interested in the disease have ersonally studied, and by the appearance of cases a district or hospital coincident with the development of an interest in hæmatology. The disease curs in primiparæ and multiparæ, and at all periods the reproductive life. Analysis of the age and parity f women affected shows little difference from the ndings in a group of normal pregnant women or in ther accidents and complications of childbirth. rimiparæ are more susceptible than multiparæ, ut the difference is not great. The disease has o relationship with the toxæmia of pregnancy or with puerperal infection. It is true that œdema and a moderate albuminuria are present in many of these anæmic women, and that they are exceptionally prone to intercurrent infection, but there is no more intimate connexion than this. Nevertheless the linical resemblance may be great, and as hæmolytic anæmia is rare, it is only natural that it should often have been confused with these much more common aladies of pregnancy, toxæmia, and infection.

CHARACTERISTICS OF THE ANÆMIA.

By the time the patients seek medical advice they are already profoundly anæmic. The early symptoms of the disease are overlooked or regarded as the ordinary discomforts of pregnancy. The anæmia increases fast as the disease approaches its climax. Extreme dyspnœa, œdema, syncopal attacks, transient blindness or paralysis, causeless hæmorrhage, uncontrollable vomiting or diarrhœa, one or more of the symptoms at last makes the patient aware that this is no normal pregnancy. The attendants are alarmed by the death-like pallor and examination of the blood reveals a severe megalocytic anæmia. The temperature is raised throughout the period of anæmia, falling to normal when improvement begins, whether spontaneously or as the result of treatment. The pallor has an icteric tinge but overt jaundice is most unusual. Urobilin is present in the urine and the indirect van den Bergh reaction is positive. Filo found that the excretion of bilirubin derivatives in the urine and fæces was increased up to three times the normal. In one case in which he made a series of estimations before and after confinement, the bilirubin excretion sank rapidly from three times the normal to subnormal at a time when the red cells were still falling; with improvement in the blood picture the bilirubin excretion was finally stabilised at the normal level. The spleen is palpable in little more than a third of all cases. In size it varies from being only just palpable to extending three or four inches below the ribs. It vanishes beneath the costal margin on repair of the anæmia. There is no evidence that enlargement of the spleen can be taken as a favourable prognostic sign, as has been suggested.[2] The liver is enlarged in a smaller fraction of cases, usually in association with the spleen but sometimes alone. Earlier writers regarded syphilis as an important ætiological factor, but its importance is not substantiated either by the clinical and post-mortem findings or by Wassermann's reaction. In 43 cases where this reaction was recorded, 35 were negative, 2 doubtful, and only 6 positive. Nor is there any instance in which antisyphilitic treatment has favourably influenced the course of the disease.

The anæmia is of the plastic type with signs of rapid regeneration of red cells, polychromasia, punctate basophilia, and nucleated red cells. The regenerative phenomena reach a climax with the remission, complete or incomplete, which occurs after labour, but they are also present before. Absence of signs of regeneration, especially after confinement, is a finding of ill omen. The fragility of the red cells seems usually to be increased as long as the patient is pregnant (Table II.). After confinement the fragility returns to normal even though the anæmia persists. The white cells are normal or increased by a polynuclear leucocytosis. A few myelocytes are found in practically every case, and they may produce a leukanæmic blood picture. Platelets are always diminished when the anæmia is severe and they may be practically absent. They rapidly return to normal values when the anæmia remits. Purpura and external hæmorrhage occur in about one-third of the cases, and there may be bleeding from the nose, the gums, or the gastro-intestinal tract. There may be vaginal hæmorrhage before the baby is born, but curiously enough the blood loss at confinement is less than normal.

Reticulocytosis before confinement was noted by Minot and by Peterson, while Evans's patient had 40 per cent. about the tenth day of the puerperium before any treatment had been given. Large numbers of megaloblasts were noted before labour by Jungmann and by Brault.

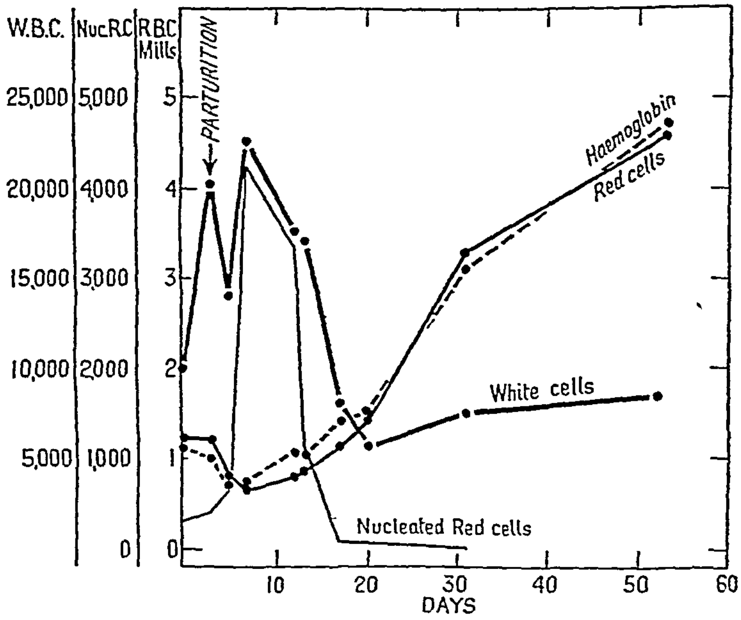
first seen four months after confinement and died five months after confinement; another did not come under treatment until seven months after confinement. The disease arises only during pregnancy and never regresses before the expulsion of the fœtus. The natural duration of the disease might be placed between three and twelve months. The strain of labour causes an exacerbation. After labour the disease terminates with an outpouring of immature red cells and rapid regeneration of the blood, but the reparative phase may be postponed for weeks or months after delivery. In Fig. 3 I have summarised the data from a 5-para, aged 29, reported by Jungmann. Her illness began about the eighth month and she was first seen a few days before delivery. No specific treatment was given. The exacerbation after labour and the spontaneous recovery with outpouring of normoblasts and megaloblasts are well shown.

FIG. 3,



Spontaneous recovery of hæmolytic anæmia of pregnancy.

Estimates of the mortality of the hæmolytic anæmia of pregnancy have steadily fallen as more cases have been collected and the death-rate of all cases reported since 1917 works out at 30 per cent. Post mortem there is œdema, anæmia, and fatty degeneration of the viscera, the spleen is enlarged, the liver shows hæmosiderosis, the bone-marrow is hyperplastic, myeloid and erythroblastic tissues are increased, and megaloblasts are present. Recovery is complete and permanent. Two of Naegeli's patients have now been under observation and remained well for thirty years. Should the patient become pregnant again however, the risk of relapse is considerable. Even one authenticated relapse would be important in a disease so rare as this. Actually the literature contains more records of relapses in subsequent pregnancies than of normal confinements.

TREATMENT.

Many drugs have been used in the treatment of the hæmolytic anæmia of pregnancy, iron, arsenic, and hydrochloric acid being the favourites, but none of them appears to have done any good. Transfusion was the only effective remedy before treatment by liver was introduced, and it remains the first remedy for patients in extremis. Four to five hundred cubic centimetres of blood should be given at a transfusion and the operation should be repeated at short intervals of time until a remission is induced. Before confinement the effect of transfusion is temporary, and it has no power to arrest the disease while the fœtus is in the uterus. After parturition it is nearly always followed by complete and rapid cure, if the patient is not too collapsed and if sufficient blood is injected. Nevertheless one of Filo's patients died five months after parturition in spite of four transfusions.

Liver has been given in many of the cases reported in recent years and the results are often quoted as proof of its curative power. It is surprising how few of the publications can be so construed. Usually liver treatment has been combined with transfusion, or it has not been prescribed till the patient was already recovering, or exact hæmatological details are lacking. Conclusive proof of the value of liver is scanty. In a few cases, however, it has been possible to arrest the progress of the anæmia before confinement, which was a very rare event before the introduction of liver therapy, and in other cases, in which the anæmia has remained torpid after confinement, treatment by liver has brought about speedy improvement.

Beckmann (1928) treated two women by parental injection of liver extract and they were able to go to term. In the case separately reported by Dyke and by Stewart and Harvey, the disease was arrested two months defore delivery by a transfusion followed by pil. ferri. grs. 5. b.d., and Liveroid 2 oz. in die. A similar case in which liver treatment was supplemented by three transfusions and the disease was arrested three months before delivery was reported by Deschamps and Froyez, and by Devraigne and Laennec (same case). Peterson's patient, who had gone downhill in spite of two transfusions, rapidly improved before delivery on a diet containing half a pound of liver a day. On the other hand, Meaker and Bongiorno failed to arrest the disease by injection of liver extract before confinement, and Wery found iron and liver ineffective in a patient who ultimately recovered after premature delivery and transfusions. The majority of the publications concern the administration of liver after delivery, and are vitiated by the absence of control periods, by the use of other forms of treatment, and by the natural tendency of the disease to get well. Nevertheless good evidence of the value of liver is provided by the following two cases. A patient of Peterson first came under treatment two months after delivery; there was a clear reticulocyte crisis and steady improvement after the administration of liver. In Lenner's patient an anæmia with high colour-index had persisted for ten months after delivery, and she likewise improved on treatment with liver.

The advisability of operative interference is still unsettled and the question waits an answer till we know more of the value of liver before confinement.

Petersen and Dyke found mean diameters of the red cells of 7·72, 8·0, and 8·16 microns. Larrabee and Wintrobe found the mean corpuscular volume increased. Price-Jones curves showing a considerable shift to the right are figured by Parvu and Fouquiau, and by Hampson and Shackle. It is unusual for the white count to be above 15,000 before labour, and high values after labour are sometimes ascribable to puerperal infection. Nevertheless a patient reported by Fabre and Trillat had 17,000 white cells per c.mm. a week before confinement, and Lenner's patient had 45,000 white cells per c.mm. with 22 per cent. of monocytes and myelocytes at the onset of labour. Large numbers of myelocytes and myeloblasts in patients who recovered are reported by Benda, Bruggemann, and Jungmann. Of great interest in early cases is the colour-index, which in Drexel's patient was high from the start. In five other cases with initial red cell counts above 2·5 millions, it was high in two (Meaker, Murdoch) and 0·7 or lower in three (Esch, Minot, Pohl). There is a good deal of evidence that the colour-index is often low at the onset, rising as the malady progresses. When the anæmia is established, the colour-index is high unless there are complications such as hæmorrhage or infection. In isolated cases the colour-index has been low throughout, though the diagnosis has been proved at post-mortem.

SYMPTOMS AND COURSE OF ILLNESS.

Digestive symptoms, stomatitis, glossitis, pharyngitis, vomiting, and diarrhœa are among the most prominent symptoms of the hæmolytic anæmia of pregnancy. It is usually difficult to date their onset, as they may follow and be inseparable from the dyspeptic troubles of the early months of pregnancy. It is probable that they do not appear till after the anæmia has developed. Most recorded early cases of hæmolytic anæmia of pregnancy have been discovered by accident in the course of a routine investigation, and the patient has had no gastro-intestinal symptoms. There are many cases in which these symptoms have first been noticed at the time of an aggravation of the anæmia during the puerperium. The inflammations about the mouth are sometimes a simple reddening and vesiculation of the mucosa, but in other patients they are ulcerous, necrotic, foul-smelling lesions. Anal gangrene has also been described. Such lesions are of course common in many cachectic states. One must therefore conclude that the gastro-intestinal disturbances are secondary to the anæmia and not primary or causative, though one must confess that their resemblance to the gastro-intestinal disturbances of pernicious and allied anæmias can be very striking.

In recent years there has been a tendency to believe that achlorhydria is present and plays an ætiological rôle in the hæmolytic anæmia of pregnancy. This belief is false and is easily traced to errors in diagnosis and to a misunderstanding of the literature. Achlorhydria is frequent in the chronic microcytic anæmia of women and in tropical macrocytic anæmia. Both of these maladies are made worse by pregnancy and are then often confused with the true hæmolytic anæmia, though they differ from it in history, symptoms, pathology, treatment, and future cou Putting aside all such cases, one finds that achlor-hydria is uncommon in the hæmolytic anæmia of pregnancy and cannot be an ætiological factor, as is clear from the following table. Not all these meals were fractional, and the true incidence of achlorhydria is probably lower than 33 per cent. In a few instances a temporary depression of gastric secretion has been observed in the period of profound anæmia.[25] [65]

The disease begins usually in the third trimester of pregnancy, but a few cases have been diagnosed as early as the fourth month and a much greater number have no symptoms until the puerperium. Drexel's case is of great interest not only because of the early diagnosis but also because of the data on the rate of development of the anæmia:—

A primigravida, aged 21, was admitted to hospital at th fourth month for pyelitis. The pyelitis cleared up in a few days but she remained pale and ill, and indeed und fatigue and anæmia became more oppressive. It wa elicited that she had always been healthy and strong u to the onset of her pregnancy, since when she had becom pale. The liver and spleen were not palpable, but ther was a moderately severe anæmia with a colour-index of 1 In spite of treatment with arsacetin injections the anæm steadily worsened, myelocytes and normoblasts appear in the peripheral blood, anorexia and vomiting set in, a there was an attack of collapse and unconsciousness lasti two hours. Her hæmoglobin having fallen to 25 per cen her pregnancy was terminated by operation at the six month, some ten weeks after admission. She then ma a rapid and spontaneous recovery, pathological c disappeared from the blood and the anæmia was repaired.

It is usually said that the anæmia becomes progressively worse during pregnancy and reaches a crisis in labour or the puerperium, which is either fatal or is followed by spontaneous recovery. This is certainly true of most of the cases which begin about the sixth or seventh month of pregnancy. Cases beginning before the sixth month often terminate in premature delivery, spontaneous or induced. Patients who have no symptoms till labour or the puerperium may remain anæmic for a long time after confinement, as in the very interesting series of cases described by Larrabee. One of these was

TREATMENT OF CLONIC FACIAL SPASM.

(*a*) BY ALCOHOL INJECTION.

(*b*) BY NERVE ANASTOMOSIS.

BY WILFRED HARRIS, M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN FOR NERVOUS DISEASES, ST. MARY'S HOSPITAL, LONDON;

AND

A. DICKSON WRIGHT, M.S. LOND., F.R.C.S. ENG.,
SUPERNUMERARY SURGEON TO OUT-PATIENTS, ST. MARY'S HOSPITAL.

TRUE clonic facial spasm is a unilateral, intermittent, or clonic series of contractions of the facial muscles, limited to one side, though not affecting the whole facial musculature to an equal degree. When once developed, spontaneous cure of clonic facial spasm is unknown.

Somewhat commoner in the female sex, the facial spasms are a source of considerable worry to the sufferers from this complaint, especially from the contractions of the orbicularis palpebrarum, or blepharospasm, causing the appearance of winking. Moreover, the sudden closure of the eye may interfere seriously with vision, as in crossing traffic, with consequent danger to life.

The onset of the spasms varies in severity and frequency, some days being comparatively free, while at other times the annoyance is excessive, aggravation being perhaps induced by nervousness or excitement. During sleep the spasms always cease. Usually these commence in the orbicularis palpebrarum, causing blepharospasm, at first slight and not to be distinguished from the intermittent contractions of this muscle which are personally familiar to many of us, and are sometimes spoken of as "live blood," and are especially liable to be brought on by fatigue. In true facial spasm, however, the muscular contractions gradually spread to other facial muscles on the same side, especially those around the angle of the mouth, and ultimately every muscle supplied by the facial nerve of one side may share in the clonic contractions, including the frontalis and platysma, and even the stapedius may be affected, the contractions being accompanied by clicking noises in the ear. This unilateral distribution of the muscular spasms distinguishes clonic facial spasm from spasmodic tic and psychomotor blepharospasm, habit spasms, chronic chorea, and other intermittent grimacing of psychical origin.

Causes of Condition.

The pathology of clonic facial spasm is unknown, though it is probably due to some form of degenerative neuritis, possibly in the neighbourhood of the geniculate ganglion, for in a well-marked case of some years' duration, it is always easy to demonstrate facial nerve weakness, contracture, and overaction on that side. Moreover, occasionally, a moderately severe *facial Bell's palsy* may be followed, in addition to the usual contracture, by well-marked clonic facial spasm (Fig. 1), indistinguishable in type and severity from that which is of gradual onset.

Undoubtedly clonic facial spasm is due to some chronic lesion or degeneration of the lower facial neuron, and is not of cortical origin, as is suggested by Gibson, who considers it as exactly parallel to spasmodic torticollis. In the latter disease the spasm is a rotary movement of the head to one side produced by the contraction of the sternomastoid of one side associated with the posterior rotators on the opposite side, in which several nerves are concerned, and no weakness of these muscles is to be detected between the spasms. In clonic facial spasm the contractions are limited to the musculature supplied by one facial nerve alone, in severe cases practically every muscle, including the platysma and stapedius, being involved.

Local injuries to the parotid region or cheek may also cause clonic spasm later on of some of the facial muscles on one side, probably due to the scarring involving facial nerve branches. No doubt such a case would not benefit by facio-hypoglossal anastomosis, as the scarring is peripheral to the site of the anastomosis.

Hemispasm of the face may occur in *cerebral lesions*, as in general paralysis, the lower quadrant of the face being chiefly involved in the spasm, and occasionally the whole facial nerve may be irritated by the presence of a *basal tumour* causing attacks of facial spasm, as has been observed in cerebellar tumour. Facial spasm has also been many times noted as a sequel to *encephalitis lethargica*.

A very remarkable combination of clonic facial spasm is occasionally met with in paroxysmal *trigeminal neuralgia*, which was described by one of us (W. H.) in 1926.

In one case, a woman aged 58, who was seen in 1921, clonic right facial spasm had commenced 30 years previously, ultimately involving the whole facial musculature of the right side, without any pain until five years before, when typical paroxysmal trigeminal neuralgia commenced. Alcohol injection of the right foramen ovale and foramen rotundum anæsthetised the second and third trigeminal areas and arrested the pain completely, but the clonic facial spasms continued unaltered until the branches of the facial nerve were injected with alcohol at the posterior border of the mandible, two days later. Ten months later, however, the clonic facial spasms were commencing to reappear, though there was no recurrence of the neuralgia.

In another case, a woman aged 52, clonic left facial spasm had developed two years previously, though paroxysmal neuralgia had commenced only five months before she was seen in May, 1916, the painful spasms then being intense, both by day and night. Injection of the Gasserian ganglion was done, which completely cured the neuralgia, which was still absent 5½ years later, though the spasmodic facial twitchings continued unaltered.

The association of clonic facial spasm with paroxysmal trigeminal neuralgia is difficult to understand, as they arise independently, and cure of the one does not affect the other. Yet they are invariably on the same side of the face, which certainly points to some real association and not coincidence. Cushing has described three cases of clonic facial spasm associated with paroxysmal trifacial neuralgia on the same side, in which Gasserian operation did not benefit the pain, but in one of which the pain disappeared after a subsequent section of the facial nerve. We have never met with such a case, though we have seen the associated pain and facial spasm in at least a dozen cases, all of which responded in the usual way to alcohol injection.

Paraspasm, or bilateral clonic spasms of the especially by injection. With other methods of treatment no lasting improvement can be expected before confinement, but the shock of operation is often mortal. It is well to remember that the disease is not so lethal to the mother as was once held, and that the majority of the babies do well. On surveying the literature I have been surprised to learn how often women who seemed moribund have spontaneously delivered themselves and recovered; and I have been impressed by the high mortality of operative interference. The conservative physician will be strengthened in his decision by the following report [8]:—

> The patient was admitted to hospital at the seventh month of pregnancy with a blood count of 750,000 red blood-cells per c.mm., hæmoglobin 25 per cent., colour-index 1·6. She refused treatment and was sent home to die. This was a journey of 70 miles over the rough mountain roads of Greece. Three days after her return she had an easy abortion and quickly got up and resumed her household tasks. She thereupon contracted pneumonia but was back at work again in three weeks, and since then has been in good health.

Discussion.

When we recapitulate the data I have collected we find good reason to separate the hæmolytic anæmias from pernicious and allied anæmias, and to subdivide the hæmolytic anæmias into acute and chronic forms. Acute hæmolytic anæmia and the hæmolytic anæmia of pregnancy differ from pernicious and allied anæmias in the absence of any nutritional or digestive defect, in the fever and general constitutional disturbance, in the regenerative character of the anæmia with reticulocytosis and leucocytosis, in the fluctuations in the resistance of the red cells, and in the self-limited course. They differ from chronic hæmolytic anæmia in clinical features, natural history, and response to treatment. They may be so acute that hæmoglobinuria develops, or they may be subacute and torpid, but death or spontaneous recovery occurs within a period rarely longer than a year. On the other hand we must be impressed by the close resemblance of acute hæmolytic anæmia and the hæmolytic anæmia of pregnancy. Every feature of the one disease is duplicated in the other, and they differ only in the fact of pregnancy. For the peculiar frequency of a disease in youth and in pregnancy we have a parallel in acute yellow atrophy of the liver. For the initiation or recrudescence of an anæmia in pregnancy we have a parallel in the bartonella anæmia of experimental animals, which may only develop under special conditions, such as after splenectomy or after artificial hæmolysis, though the micro-organisms were previously present in the host. There is no valid reason in pathology for the separation of acute hæmolytic anæmia and the hæmolytic anæmia of pregnancy, and every symptom points to their identity.

To-day one can do no more than present this group of cases and demonstrate their natural features and course. If they are due to infection, as seems probable from the clinical picture, we must look for a different organism from the pyogenic cocci, something perhaps more akin to bartonella. I know no other human infection which responds in this way to transfusion or liver, but there is evidence that *Bartonella muris* can be cured by liver.[78] Writers on the hæmolytic anæmia of pregnancy have referred to the acceleration of blood breakdown and repair entailed by pregnancy, and the hæmolysis of maternal corpuscles in the placenta and elsewhere to supply hæmopoietic material for the fœtus. They have felt that hæmolytic anæmia in pregnancy may be a morbid exaggeration of this process, such as I have already described in icterus gravis neonatorum, and the serum has many times been examined for hæmolysins, but without success. It is a possible but unlikely explanation of all these acute anæmias that they are breakdowns of the normal rhythm of erythropoiesis and erythrolysis, comparable with a disturbance in the rhythm of the heart-beat and that the fever and constitutional disturbance are secondary effects. It has been my aim in this lecture not to construct theories, but to bring together a great number of scattered observations and to show the common characteristics of these acute anæmias.

TREATMENT OF CLONIC FACIAL SPASM.

(a) BY ALCOHOL INJECTION.

(b) BY NERVE ANASTOMOSIS.

By WILFRED HARRIS, M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN FOR NERVOUS DISEASES, ST. MARY'S HOSPITAL, LONDON;

AND

A. DICKSON WRIGHT, M.S. LOND., F.R.C.S. ENG.,
SUPERNUMERARY SURGEON TO OUT-PATIENTS, ST. MARY'S HOSPITAL.

TRUE clonic facial spasm is a unilateral, intermittent, or clonic series of contractions of the facial muscles, limited to one side, though not affecting the whole facial musculature to an equal degree. When once developed, spontaneous cure of clonic facial spasm is unknown.

Somewhat commoner in the female sex, the facial spasms are a source of considerable worry to the sufferers from this complaint, especially from the contractions of the orbicularis palpebrarum, or blepharospasm, causing the appearance of winking. Moreover, the sudden closure of the eye may interfere seriously with vision, as in crossing traffic, with consequent danger to life.

The onset of the spasms varies in severity and frequency, some days being comparatively free, while at other times the annoyance is excessive, aggravation being perhaps induced by nervousness or excitement. During sleep the spasms always cease. Usually these commence in the orbicularis palpebrarum, causing blepharospasm, at first slight and not to be distinguished from the intermittent contractions of this muscle which are personally familiar to many of us, and are sometimes spoken of as "live blood," and are especially liable to be brought on by fatigue. In true facial spasm, however, the muscular contractions gradually spread to other facial muscles on the same side, especially those around the angle of the mouth, and ultimately every muscle supplied by the facial nerve of one side may share in the clonic contractions, including the frontalis and platysma, and even the stapedius may be affected, the contractions being accompanied by clicking noises in the ear. This unilateral distribution of the muscular spasms distinguishes clonic facial spasm from spasmodic tic and psychomotor blepharospasm, habit spasms, chronic chorea, and other intermittent grimacing of psychical origin.

Causes of Condition.

The pathology of clonic facial spasm is unknown, though it is probably due to some form of degenerative neuritis, possibly in the neighbourhood of the geniculate ganglion, for in a well-marked case of some years' duration, it is always easy to demonstrate facial nerve weakness, contracture, and overaction on that side. Moreover, occasionally, a moderately severe *facial Bell's palsy* may be followed, in addition to the usual contracture, by well-marked clonic facial spasm (Fig. 1), indistinguishable in type and severity from that which is of gradual onset.

Undoubtedly clonic facial spasm is due to some chronic lesion or degeneration of the lower facial neuron, and is not of cortical origin, as is suggested by Gibson, who considers it as exactly parallel to spasmodic torticollis. In the latter disease the spasm is a rotary movement of the head to one side produced by the contraction of the sternomastoid of one side associated with the posterior rotators on the opposite side, in which several nerves are concerned, and no weakness of these muscles is to be detected between the spasms. In clonic facial spasm the contractions are limited to the musculature supplied by one facial nerve alone, in severe cases practically every muscle, including the platysma and stapedius, being involved.

Local injuries to the parotid region or cheek may also cause clonic spasm later on of some of the facial muscles on one side, probably due to the scarring involving facial nerve branches. No doubt such a case would not benefit by facio-hypoglossal anastomosis, as the scarring is peripheral to the site of the anastomosis.

Hemispasm of the face may occur in *cerebral lesions*, as in general paralysis, the lower quadrant of the face being chiefly involved in the spasm, and occasionally the whole facial nerve may be irritated by the presence of a *basal tumour* causing attacks of facial spasm, as has been observed in cerebellar tumour. Facial spasm has also been many times noted as a sequel to *encephalitis lethargica*.

A very remarkable combination of clonic facial spasm is occasionally met with in paroxysmal *trigeminal neuralgia*, which was described by one of us (W. H.) in 1926.

In one case, a woman aged 58, who was seen in 1921, clonic right facial spasm had commenced 30 years previously, ultimately involving the whole facial musculature of the right side, without any pain until five years before, when typical paroxysmal trigeminal neuralgia commenced. Alcohol injection of the right foramen ovale and foramen rotundum anæsthetised the second and third trigeminal areas and arrested the pain completely, but the clonic facial spasms continued unaltered until the branches of the facial nerve were injected with alcohol at the posterior border of the mandible, two days later. Ten months later, however, the clonic facial spasms were commencing to reappear, though there was no recurrence of the neuralgia.

In another case, a woman aged 52, clonic left facial spasm had developed two years previously, though paroxysmal neuralgia had commenced only five months before she was seen in May, 1916, the painful spasms then being intense, both by day and night. Injection of the Gasserian ganglion was done, which completely cured the neuralgia, which was still absent 5½ years later, though the spasmodic facial twitchings continued unaltered.

The association of clonic facial spasm with paroxysmal trigeminal neuralgia is difficult to understand, as they arise independently, and cure of the one does not affect the other. Yet they are invariably on the same side of the face, which certainly points to some real association and not coincidence. Cushing has described three cases of clonic facial spasm associated with paroxysmal trifacial neuralgia on the same side, in which Gasserian operation did not benefit the pain, but in one of which the pain disappeared after a subsequent section of the facial nerve. We have never met with such a case, though we have seen the associated pain and facial spasm in at least a dozen cases, all of which responded in the usual way to alcohol injection.

Paraspasm, or bilateral clonic spasms of the median musculature of the face, has been described by Sicard and Haguenau. It is clearly of cerebral origin, and is probably allied to the tics and habit spasms. These are easily distinguished from true clonic facial spasm, which is almost invariably unilateral.

Bilateral *blepharospasm* also is a psychomotor reflex, which may be started by sudden exposure to bright light, or the irritation from conjunctivitis or snow blindness, and it may also become chronic after the emotional reflex of a bout of crying. Sometimes it may be cured by local nerve injection or section, but psychotherapy should always first be employed.

Treatment.

The treatment of clonic facial spasm has in the past been most unsatisfactory. Electricity and massage are worse than useless, as also are blisters and other counter-irritants applied behind the ear. Exposing the facial nerve by open operation behind the angle of the jaw, and then stretching the nerve has been tried in the past, with only temporary success. Simple division of the nerve will arrest the spasm for a time, by producing complete facial paralysis, but recovery is almost certain to take place, owing to some re-establishment of conduction of the nerve-fibres, with consequent return of the clonic spasms. The degree of deformity in the case of a freshly divided nerve in these cases is not nearly so intense as would result in a recent case of total facial palsy from other causes, because, as we said above, there is always present in long-standing cases a certain amount of facial contracture, which diminishes the amount of facial deformity produced by section of the nerve.

Recently, Frazier has advocated his method of dividing by open operation the nerve-fibrils to the orbicularis palpebrarum and corrugator for the treatment of blepharospasm. Incisions are made across the zygoma in front of the parotid, but these must produce at best scars unpleasant for a female subject, and would not affect the spasms of the angle of the mouth or of the remaining musculature.

Alcohol injection of the nerve at its exit from the stylomastoid foramen has been tried, without good results. If the nerve is properly hit, the facial paralysis will be as severe as if the nerve were cut, though recovery will ultimately take place, with recurrence of the clonic spasms. It is by no means an easy matter to inject the stylomastoid foramen, and searching for the foramen is usually a very painful process.

A method of alcohol injection (Schloesser) that has been used by one of us (W. H.) during the last few years with considerable success, though the relief from the spasms may not last more than three to six months, is to inject the two main branches of the facial nerve where they cross the posterior border of the mandible in front of the ear. This can be easily and fairly quickly done, with practice, under local novocain only, with very little pain, and this method has the advantage that either or both of these branches can be injected at will.

If the spasms are limited to the region around the eye, with no clonic spasms of the angle of the mouth, the upper branch only should be injected, and frequently this is all that is necessary.

A fine hypodermic needle is used, and two Record syringes, one filled with 2 per cent. novocain solution, and the other with 90 per cent. alcohol (spir. vini. rect.). A horizontal mark is made with a dermatographic pencil on the skin at the back of the mandible to mark the level of the crossing of the facial nerve over the posterior border of the bone. This is done by pressing the left index-finger in front of the mastoid process and below the external auditory meatus, and then marking the level of the upper edge of the finger. Another vertical line should be drawn downwards to mark the posterior border of the mandible. The hypodermic needle attached to the novocain syringe is now inserted through the skin at the junction of the two lines, and pushed directly down to the posterior edge of the mandible, which should be felt by the needle point. This is then slipped backwards over the posterior edge and directed slightly upwards, and three or four drops of novocain solution injected, moving the needle slightly upwards and downwards.

Then keeping the needle still, the alcohol syringe is fitted on, and after half a minute four or five drops of alcohol injected, moving the needle as before slightly upwards and downwards while doing so, and very slightly deeper than the posterior edge of the bone. Almost at once it will be found that the eyelid cannot be closed against resistance, and increasing weakness of the frontalis and corrugator also develop, while the angle of the mouth remains unaffected. In those cases in which the spasms affect the lower facial muscles also, the needle should now be partially withdrawn and inserted down to the bone pointing slightly downwards, then slipped over the posterior edge, and the injection of novocain and alcohol made as before. At once the muscles moving the angle of the mouth and the orbicularis oris will commence to weaken, and the amount of paresis can be regulated by the amount of alcohol injected.

When both branches of the facial nerve are injected in this way, the resulting facial paresis may be partial or total according to the amount of alcohol injected. It is interesting to notice that in those cases in which clicking noises in the ear accompany the clonic facial spasms, these noises continue after the facial spasms have been completely arrested by the facial paralysis produced. This is because the nerve-supply to the stapedius muscle is on the proximal side of the alcohol injection, being given off within the middle ear. Yet within a day or two these clicking noises always disappear, probably owing to a reflex effect of the nerve paralysis upon the ganglionic nerve centres, inhibiting the efferent discharges from above.

Although the relief from the clonic facial spasms thus produced is immediate, it is unlikely to be permanent, as with the repair of the nerve-fibres the path for the efferent nervous discharges is re-established, and the clonic spasms reappear gradually in three to six months as a rule, though sometimes twelve months or even longer relief is obtained.

NERVE ANASTOMOSIS.

In order to obtain a permanent cure, the facial nerve must be divided, and its peripheral portion permanently separated from the irritable centre above. With that end in view, and in order to avoid permanent facial palsy, nerve anastomosis with the hypoglossal was decided on by one of us (W. H.) So far as we are aware, only two nerve anastomosis operations for facial spasm have previously been recorded. Kennedy in 1899 performed end-to-end anastomosis of the facial and spinal accessory nerve for facial spasm with fairly successful result, and in 1921 Gibson performed end-to-end facio-hypoglossal anastomosis for the same condition. Gibson gives a good résumé of previous work on facial nerve anastomosis, with records of several cases of his own, all but one done for facial paralysis.

In several no recovery was seen until from six to ten months had elapsed after the operation, though good voluntary and associated movements returned and convincing photographs are shown, though it is probable that emotional use of the facial muscles was confined in all to the unaffected side. This is only to be expected when we consider that for the return of such emotional movements it would be necessary for the facial cortical centre to develop new paths for the conduction of impulses to the hypoglossal nucleus, which appears most unlikely to happen, or else that the cortical centre for the tongue movements should develop an association link with the facial centre, that they should work in tandem, so to speak. This theory seems an attractive possibility, and its development may probably be encouraged by persistent and steady practising by the patient, in front of a mirror, of combinations of voluntary movements or emotional movements of the face with various tongue movements.

Our first case, Mrs. A. aged 50, was operated on by Mr. Blundell Bankart in February 1930, employing end-to-end suture, and partial motor recovery of the face has been present for the past eighteen months, with no return of the clonic spasms, from which she had suffered, on the right side, for seven years.

Her present condition shows, of course, hemiatrophy of the tongue, but she does not notice any disability from this. At rest, the face shows very little deformity, but there is so far no return of voluntary power in any of the facial muscles, apart from those associated with synchronous movements of the tongue. During talking, the eyelid is seen to close slightly, and the nasolabial fold to deepen, while if the tongue is pressed forwards against the teeth there is seen strong contraction of the zygomatici and of the orbicularis palpebrarum. Showing the teeth, smiling, pursing up the lips, or wrinkling the forehead show no return yet of voluntary power, and this is only to be expected, inasmuch as it must take much longer for conducting paths to become established between the facial cortical centres and the hypoglossal nucleus, than for impulses normally sent from the hypoglossal nucleus to the tongue muscles to reach the facial muscles through the anastomosis. Such movements should normally commence to appear as soon as the new *hypoglossal* fibres can grow down along the peripheral portion of the divided facial nerve, which appears to be three months, almost exactly.

She has been told to practise daily making facial movements in front of a mirror, and thus to aid the development of independent facial movements should the necessary intramedullary nervous paths of conduction to the hypoglossal nucleus begin to function.

FIG. 3. FIG. 4.

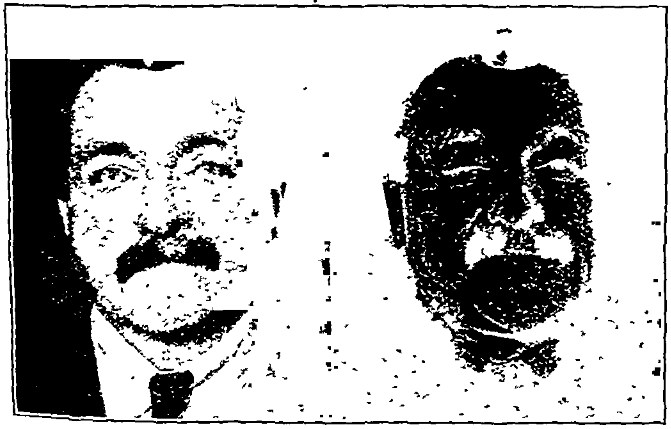

FIG. 3.—Man, aged 51, showing face at rest 10 months after the nerve anastomosis operation.

FIG. 4.—Showing associated contraction of the eyelids and angle of the mouth on the operated side when he pushes his tongue forwards against his teeth.

During the past year four more cases have been operated on by one of us (A. D. W.), 10, 6, 5, and 3 months ago respectively, and of these the first case has been done long enough to report upon, while the second case began to develop associated movements of the eyelid and the angle of the mouth with the tongue at the end of three months. The third case (Fig. 1) has not after five months yet shown any power of contraction of the paralysed muscles, though tonus is returning as she notices her face is much straighter. Even if no further recovery should take place, she is quite pleased to have got rid of the constantly recurring facial spasms. There is plenty of time yet, however, for recovery to ensue, for several of Gibson's and other published cases show an interval as long as ten months before return of power was evident.

FIG. 1. FIG. 2.

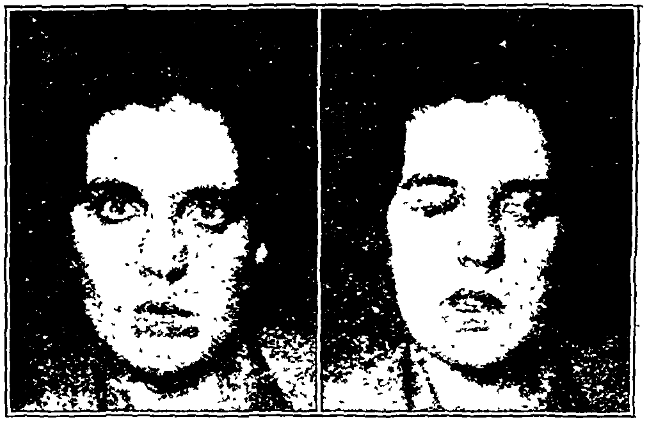

FIG. 1.—Woman, aged 23. Left mastoid operation 11 years ago, immediately followed by complete left facial palsy. Six years later clonic facial spasm commenced at the angle of the mouth, gradually becoming violent. Left facio-hypoglossal anastomosis operation June 29th, 1931. The photograph shows the face at rest, a few days after the nerve anastomosis.

FIG. 2.—Patient is now attempting to smile and to close the eyes. No voluntary or associated movements on the paralysed side have yet appeared.

Mr. B., aged 51, first noticed a twitching in the right lower eyelid in 1915. He could not trace the onset of this to any cause, but from the commencement the twitching has never left him entirely, and has gradually grown worse, until he had great difficulty in getting the eye open at times. He abandoned his trade of shoemaking because he was always being unsighted when the eye closed involuntarily. On testing the facial movements, there was definite slight paresis of all the facial movements on the right side, with overaction and contracture shown when making any strong movement such as closing the eyes forcibly. Spontaneous spasms at times were strong, closing the eye completely, and drawing the angle of the mouth strongly towards the right.

He was operated on, Feb. 23rd, 1931, the technique outlined below being followed. The post-operative course was normal, and he went home on the tenth day, wearing a Jennings splint, with instructions to massage and support his face. From that time until recently he attended the Aldershot Hospital for electrical treatment. At the time of writing many of the facial muscles show a return of movement when the tongue is pressed forwards (see Figs. 3 and 4), especially the orbicularis palpebrarum and the zygomatici, and during speech a slight flickering of the muscles around the eye and the angle of the mouth can be seen synchronous with the tongue movements. Voluntary movements of the facial muscles alone, without tongue movements, are still absent, but the improvement so far is hopeful, and he is very satisfied and pleased to have got rid of the spasms, even if no further voluntary movement should return.

The treatment by division of the nerve is sure to result in abolition of the spasm, but it is essential to endeavour to improve the facial deformity resulting, so that the patient will not consider it a doubtful bargain to have exchanged a facial twitch for a facial palsy, though as already explained, owing to the contracture existing, the facial palsy produced is scarcely noticeable at rest. The surgical problem is somewhat simpler than that of facial paralysis, because the paralysis is produced at the time the anastomosis is made. There is not a long intervening period of time during which the distal part of the nerve and the facial muscles have undergone degeneration.

OTHER METHODS.

The multiplicity of operations suggested for facial paralysis indicates that none is entirely satisfactory. Plastic operations by insertion of fascial or silk loops to correct the sagging of the lower lid, the ala nasi, and the corner of the mouth, are usually reserved for cases where nerve anastomosis is impossible or has been a failure.

Myoplasty is sometimes of value, using muscles with or without their nerve-supply, to correct the drooping of the corner of the mouth and lower eyelid. The temporal muscle, the masseter (Lexer), and sternomastoid (Gomoiu) have been used, and Jianu has suggested using the stylohyoid or the posterior belly of the digastric, because these muscles are innervated by the facial nerve, although they can hardly be regarded as muscles of facial expression. Division of the cervical sympathetic is very favoured by the school of surgery led by Leriche. They argue that the eye changes of Horner's syndrome neutralise the disfigurement of facial paralysis, and even assert that the facial muscles will move on the paralysed side if the cervical sympathetic is cut on that side. Bourguignon has gone so far as to say that the facial nerve sends a branch across the mid-line to the orbicularis palpebrarum, and this nerve produces contractions if the antagonistic sympathetic impulses are withdrawn. In this connexion it is interesting to note that Sicard, Robineau, and Haguenau have reported two cases of clonic spasm of the face treated by simultaneous division of the facial nerve and cervical sympathetic. It is also claimed that the diminution in lacrymal secretion following sympathectomy removes the "unshed tear" appearance which results from facial palsy.

VARIETIES OF ANASTOMOSIS.

Treatment of facial paralysis by anastomosis with adjoining nerves has found more favour in this country, and valuable pioneer work in this connexion was done by Ballance. The nerves suggested for anastomosis are: (1) the spinal accessory in whole or in part (Ballance, 1895); (2) the glossopharyngeal (Schäffer); (3) the hypoglossal in whole or in part (Koerte); (4) the descendens noni or cervicalis or both (Rawa); (5) the cervical sympathetic (Ballance); (6) anastomosis of the facial to the hypoglossal, combined with anastomosis of the ansa hypoglossi to the distal end of the hypoglossal, to neutralise lingual atrophy (Brown).

Koerte was the first to perform facio-hypoglossal anastomosis for the treatment of chronic facial paralysis, and Ballance and many others have adopted this procedure, end-to-end anastomosis being found far more satisfactory in results than end-to-side anastomosis. Ballance (1909) also united the distal end of the cut hypoglossal to the central end of half of the spinal accessory nerve, which he split for this purpose, and he claimed that 20 months later the nutritional and functional recovery of the facial, lingual, and cervical muscles was complete, and that the movements of the face and tongue were dissociated. His photographs scarcely bear out that statement in its entirety at least, as his Fig. 4, in which the tongue is protruded, shows clearly the overaction of the zygomatici on the paralysed side, associated with the protrusion of the tongue, just as we have observed in our cases. Ballance says that in his case the movements due to emotional stimuli were symmetrica and perfect, but he quotes Bernhardt as stating that after operations for facio-hypoglossal anastomosi the associated movements recovered, and som voluntary power of the face, yet the norma symmetrical play of the facial muscles in th expression of emotions was not regained. Certainl our results are so far more comparable to the latte description than to that of Ballance.

It is too much to hope that the complicated an delicate movements of facial expression can ever b entirely reproduced by means of any other nerv and one can only hope to restore tone and mobilit to the face. The anastomosis giving the best resul at present is that with the hypoglossal. This nerv is a very active one, so a good tone is given to th facial muscles, and also there is considerable animati in the face in speech, involving as it does movemen of both tongue and lips. The hemiparalysis of th tongue is not found to be of much inconvenience eith in mastication or in speaking.

THE OPERATION RECOMMENDED.

The operation is carried out as follows:—

The skin incision can be nicely placed as a rule along crease of the skin, from the mastoid process to the neighbo hood of the cornu of the hyoid. In men, this incision c only with difficulty be distinguished from a fold in the ne after a few months time, and in women *it does not constit* a serious disfigurement. It is well to find the facial ne first of all, because it is the more difficult of the two. T posterior belly of the digastric muscle must be clea defined and its nerve of supply if possible identified, beca it is an excellent guide to the facial nerve from which arises.

The facial nerve can then be dissected out from fatty tissue lying deep to the parotid gland; Kelly's co *is an excellent instrument for this* rather difficult dissecti It is most essential to carry the dissection as close to stylomastoid foramen as possible before dividing the ner so as to give as great a length of nerve as possible to br down to the hypoglossal. Halstead's manœuvre of saw *through and reflecting the mastoid* process is sometimes value in difficult cases, to facilitate the exposure of facial nerve. The hypoglossal nerve is generally qu easily found hooking round the occipital artery. T dissection of this nerve is carried to the base *of the ton* *until a large branch is seen to be given off*, then the ne is divided just proximal to this branch.

The peripheral end of the facial nerve and the proxi end of the hypoglossal are brought together and held b temporary catgut stitch which must be passed with atraumatic needle and tied with *the first turn* only o surgeons knot, the ends of the thread are not cut and se to steady the nerve and maintain apposition while stitches through the perineurium are passed. The stitc through the perineurium are of silk of such fineness as to almost invisible. It is prepared by separating *the constitu* strands of the finest surgical silk. Bishop Harman's corn loup is worn during this part of the operation to magn the field. After a row of these fine sutures *have b* passed, uniting the perineural sheaths, the catgut hold stitch is divided and removed, and *it will now be obser* that the suture line is almost impossible to distingu from the rest of the nerve. So much depends upon perfection of this anastomosis that it should be done w the utmost care, and with no consideration of the ti involved.

Having completed the anastomosis, half of the thickn of the digastric muscle is turned forward as a flap from mastoid process and passed over the nerve, and resutured in place, thus the line of anastomosis lies in the substance of this muscle. It is a well-known fact that muscle is the ideal bed for a regenerating nerve (Robert Jones), and the suture line of the nerve should never be left in fatty or fibrous tissue, as the resultant cicatrisation endangers the regeneration. The perfect closure of the perineurium prevents the wandering of the regenerating nerve fibrils, and also prevents inflammatory cells wandering between the cut ends of the nerve, and increasing the cicatrisation.

An absolutely dry wound is secured before closing the fascia with interrupted fine catgut stitches. The skin incision is carefully sutured with a Halsted's subcuticular stitch and a firm even pressure maintained over the operation field by means of a piece of sponge rubber, cut to fit in behind the angle of the jaw, and kept in place by a bandage. The attention to absolute hæmostasis and the prevention of post-operative collection of serum by firm pressure is of the first importance.

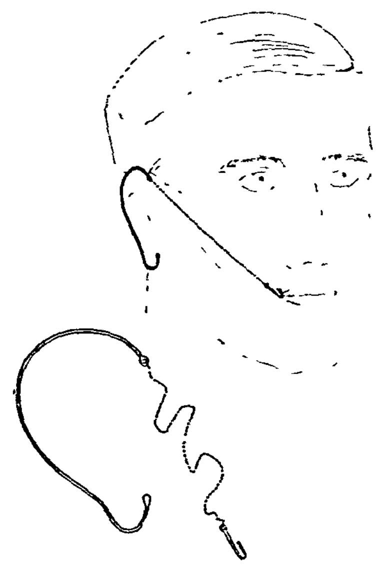
Various reasons for failure of nerve anastomosis have been suggested.

1. Trauma to the nerve ends. This must be prevented by dividing the nerve cleanly at right angles with a knife, because scissors crush before cutting, and by refraining from picking up the nerve with forceps. The best instrument to steady the nerve for the passing of the guide stitch is a Gillies' hook. Once the guide stitch is in position no further manipulation of the nerve is necessary.

2. The formation of a post-operative hæmatoma and collection of serum leading to excessive scar formation may be prevented by accurate hæmostasis and a pressure dressing.

3. Cicatrisation at the site of the anastomosis is reduced to a minimum if the suture line is buried in the muscle. The enclosure of the anastomosis in an excised segment of vein is not regarded as so satisfactory as the burying of the suture line in muscle.

FIG. 7.



Chain and hook splint, made by Hamblin, Wigmore-street.

4. The use of unsuitable suture material. The outcome of war-time experience in man, and experiments in animals (Sargent), seems to point to silk as the best suture material, and naturally the finer the material the less irritation is caused. Chromicised catgut is regarded as most unsuitable for nerve suture.

POST-OPERATIVE CARE.

The post-operative care is of some importance to ensure a successful outcome to the operation. The patient stays in bed no longer than he feels inclined, and is usually walking on the afternoon following the day of the operation. The wound is not dressed until the tenth day, when the subcuticular stitch is removed. At this time galvanic stimulation of the paralysed muscles is commenced, and is continued steadily until facial movements return. It is probably best for the patient to have his own battery, and to treat the muscles two or three times daily for ten minutes. Massage should also be employed by the patient's finger to pull up the lower lid, the ala nasi, the frontalis, and the corner of the mouth, by stroking movements.

FIG. 5. FIG. 6.

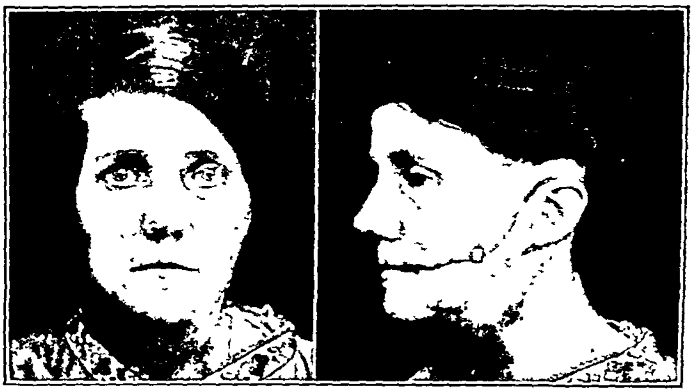


FIG. 5.—Woman, aged 41, showing the face at rest 24 hours after left facio-hypoglossal anastomosis, Nov. 28th, 1931.

FIG. 6.—Patient is wearing a Jennings splint. The scar of the operation in the neck is also shown.

When reading or writing, the elbow should be rested on the table, and the paralysed side of the face supported by the palm of the hand; this is moreover a position frequently adopted naturally. When sleeping, the patient should lie on the affected side to give support to the facial muscles.

A facial splint is of great value (Dennis); either Miss Jennings's splint of German silver wire (Fig. 6) or the chain splint made for one of us (W. H.) by Hamblin of Wigmore-street (Fig. 7). The splint prevents overstretching of the zygomaticus and the levator anguli oris, and also prevents the cheek from puffing out, due to the weak buccinator.

Careful attention to the operative and post-operative details will lead to a measure of success in practically all cases, with a very fair cosmetic result. Gibson, in 1921, and Brown, in 1926, published photographs of cases with very fair results following this operation performed for facial palsy.

In the case of clonic facial spasm, how much more certain must be the outlook for return of facial movement when we are dealing with the freshly sectioned facial nerve and facial muscles in perfect condition, and no previous scarring from inflammation in the mastoid region. We therefore feel that it is justifiable to embark upon the procedure of facio-hypoglossal anastomosis in cases which cannot be sufficiently relieved by alcohol injection, and in which the spasms constitute a great source of annoyance, and even disability to the patient.

The treatment by division of the nerve is sure to result in abolition of the spasm, but it is essential to endeavour to improve the facial deformity resulting, so that the patient will not consider it a doubtful bargain to have exchanged a facial twitch for a facial palsy, though as already explained, owing to the contracture existing, the facial palsy produced is scarcely noticeable at rest. The surgical problem is somewhat simpler than that of facial paralysis, because the paralysis is produced at the time the anastomosis is made. There is not a long intervening period of time during which the distal part of the nerve and the facial muscles have undergone degeneration.

OTHER METHODS.

The multiplicity of operations suggested for facial paralysis indicates that none is entirely satisfactory. Plastic operations by insertion of fascial or silk loops to correct the sagging of the lower lid, the ala nasi, and the corner of the mouth, are usually reserved for cases where nerve anastomosis is impossible or has been a failure.

Myoplasty is sometimes of value, using muscles with or without their nerve-supply, to correct the drooping of the corner of the mouth and lower eyelid. The temporal muscle, the masseter (Lexer), and sternomastoid (Gomoiu) have been used, and Jianu has suggested using the stylohyoid or the posterior belly of the digastric, because these muscles are innervated by the facial nerve, although they can hardly be regarded as muscles of facial expression. Division of the cervical sympathetic is very favoured by the school of surgery led by Leriche. They argue that the eye changes of Horner's syndrome neutralise the disfigurement of facial paralysis, and even assert that the facial muscles will move on the paralysed side if the cervical sympathetic is cut on that side. Bourguignon has gone so far as to say that the facial nerve sends a branch across the mid-line to the orbicularis palpebrarum, and this nerve produces contractions if the antagonistic sympathetic impulses are withdrawn. In this connexion it is interesting to note that Sicard, Robineau, and Haguenau have reported two cases of clonic spasm of the face treated by simultaneous division of the facial nerve and cervical sympathetic. It is also claimed that the diminution in lacrymal secretion following sympathectomy removes the "unshed tear" appearance which results from facial palsy.

VARIETIES OF ANASTOMOSIS.

Treatment of facial paralysis by anastomosis with adjoining nerves has found more favour in this country, and valuable pioneer work in this connexion was done by Ballance. The nerves suggested for anastomosis are: (1) the spinal accessory in whole or in part (Ballance, 1895); (2) the glossopharyngeal (Schäffer); (3) the hypoglossal in whole or in part (Koerte); (4) the descendens noni or cervicalis or both (Rawa); (5) the cervical sympathetic (Ballance); (6) anastomosis of the facial to the hypoglossal, combined with anastomosis of the ansa hypoglossi to the distal end of the hypoglossal, to neutralise lingual atrophy (Brown).

Koerte was the first to perform facio-hypoglossal anastomosis for the treatment of chronic facial paralysis, and Ballance and many others have adopted this procedure, end-to-end anastomosis being found far more satisfactory in results than end-to-side anastomosis. Ballance (1909) also united the distal end of the cut hypoglossal to the central end of half of the spinal accessory nerve, which he split for this purpose, and he claimed that 20 months later the nutritional and functional recovery of the facial, lingual, and cervical muscles was complete, and that the movements of the face and tongue were dissociated. His photographs scarcely bear out that statement in its entirety at least, as his Fig. 4, in which the tongue is protruded, shows clearly the overaction of the zygomatici on the paralysed side, associated with the protrusion of the tongue, just as we have observed in our cases. Ballance says that in his case the movements due to emotional stimuli were symmetrical and perfect, but he quotes Bernhardt as stating that after operations for facio-hypoglossal anastomosis the associated movements recovered, and some voluntary power of the face, yet the normal symmetrical play of the facial muscles in the expression of emotions was not regained. Certainly our results are so far more comparable to the latter description than to that of Ballance.

It is too much to hope that the complicated and delicate movements of facial expression can ever be entirely reproduced by means of any other nerve, and one can only hope to restore tone and mobility to the face. The anastomosis giving the best results at present is that with the hypoglossal. This nerve is a very active one, so a good tone is given to the facial muscles, and also there is considerable animation in the face in speech, involving as it does movements of both tongue and lips. The hemiparalysis of the tongue is not found to be of much inconvenience either in mastication or in speaking.

THE OPERATION RECOMMENDED.

The operation is carried out as follows:—

The skin incision can be nicely placed as a rule along a crease of the skin, from the mastoid process to the neighbourhood of the cornu of the hyoid. In men, this incision can only with difficulty be distinguished from a fold in the neck after a few months time, and in women it does not constitute a serious disfigurement. It is well to find the facial nerve first of all, because it is the more difficult of the two. The posterior belly of the digastric muscle must be clearly defined and its nerve of supply if possible identified, because it is an excellent guide to the facial nerve from which it arises.

The facial nerve can then be dissected out from the fatty tissue lying deep to the parotid gland; Kelly's comb is an excellent instrument for this rather difficult dissection. It is most essential to carry the dissection as close to the stylomastoid foramen as possible before dividing the nerve, so as to give as great a length of nerve as possible to bring down to the hypoglossal. Halstead's manœuvre of sawing through and reflecting the mastoid process is sometimes of value in difficult cases, to facilitate the exposure of the facial nerve. The hypoglossal nerve is generally quite easily found hooking round the occipital artery. The dissection of this nerve is carried to the base of the tongue until a large branch is seen to be given off, then the nerve is divided just proximal to this branch.

The peripheral end of the facial nerve and the proximal end of the hypoglossal are brought together and held by a temporary catgut stitch which must be passed with an atraumatic needle and tied with the first turn only of a surgeons knot, the ends of the thread are not cut and serve to steady the nerve and maintain apposition while the stitches through the perineurium are passed. The stitches through the perineurium are of silk of such fineness as to be almost invisible. It is prepared by separating the constituent strands of the finest surgical silk. Bishop Harman's corneal loup is worn during this part of the operation to magnify the field. After a row of these fine sutures have been passed, uniting the perineural sheaths, the catgut holding stitch is divided and removed, and it will now be observed that the suture line is almost impossible to distinguish from the rest of the nerve. So much depends upon the perfection of this anastomosis that it should be done with the utmost care, and with no consideration of the time involved.

Having completed the anastomosis, half of the thickness of the digastric muscle is turned forward as a flap from the as indicative of increased functional activity. Other observers have held that the changes are degenerative in nature, but Evans and Simpson[11] have found that bilateral gonadectomy, performed prior to removal of an animal's pituitary for transplantation experiments, increases the potency of such transplants, and Zondek[1] and Fluhmann[3, 12] have demonstrated the presence of prolan A in the urine and blood-serum of patients, after bilateral oöphorectomy. These two facts seem to prove conclusively that the pituitary changes are not degenerative but hyperplastic.

Zondek states that after castration the follicle-ripening hormone can be found in the urine in quantities as large as 150 R.U. (rat units) per litre.

An attempt was made to verify these findings. The result was that, of four patients under the menopausal age who had bilateral oöphorectomy without an ovarian graft, two showed prolan A in the urine after operation. In one, the hormone appeared as early as the eleventh day after castration, but was not present later; in the other, it was not found until six weeks after removal of the ovaries. This small number of cases does not enable one to say at what times the hormone usually appears and disappears; but Fluhmann[3] obtained a positive result as early as the ninth day, and as late as fourteen years after the operation. He also found that the urines from some patients, which had been negative at first, became positive later. In one of my cases prolan A, although present at first, disappeared later; this seems to imply that its occurrence is merely a temporary effect of the general endocrine disturbance.

This variation in the time of the appearance of the hormone is in accordance with the findings of Rössle[13] who observed that the changes in the pituitary developed sometimes as early as five days after castration, while in others a considerable time elapsed before they were manifest.

This over-activity of the hypophysis, since it occurs both at the menopause and after castration, is probably due to the removal of ovarian stimulation. As to what ovarian factor is concerned there is some dispute. Kraul[14] quotes the investigations of other workers which appeared to show that injections of œstrin, after castration, prevented the changes in the anterior pituitary. However, Fluhmann and Kulchar[15] claim to have demonstrated that the appearance of what they call "castration" cells in the hypophysis, is not related to a diminished amount of œstrin. Fluhmann[3] found that the constant administration of the follicular hormone to castrated rats over a period of three months failed to prevent the the typical pituitary changes. But Mahnert and Siegmund[16] observed that injections of œstrin into a normal animal delays ovulation, and since the latter event is now believed to be dependent on the pituitary, it is probable that an excess of œstrin in the body diminishes the prolan A output, and vice versa.

On this assumption, it is possible to explain the periodic ripening of the normal Graafian follicle. When no follicle is ripe, and no œstrin is formed or is circulating in the blood stream, the hypophysis secretes the follicle-ripening hormone. This leads to the production of œstrin which inhibits the pituitary and prevents, for the time being, the secretion of prolan A.

In three further cases which I have studied, the patients were past the menopause before their ovaries were removed, and none of them had any prolan A in the urine—a finding in conformity with the above hypothesis. In three other cases of oöphorectomy the patients had an ovarian graft in the rectus abdominis muscle. One would expect that in these cases pituitary hormone would not have been found in the urine, yet it occurred in considerable quantities in two of the patients. However, inquiries into the operative details of these two cases revealed the fact that in both of them the ovaries were so diseased that only a very small portion was available for grafting. Although in one patient this was sufficient to promote the continuance of menstruation one can imagine that there would be a considerable reduction in the amount of œstrin produced, especially as an attempt was made by the operator to remove the follicle-bearing area from the transplanted ovarian tissue.

It is interesting to note that Fluhmann[3] found that whereas, after operative or radiation castration, at the menopause, and in some patients with prolonged periods of amenorrhœa, the follicle-stimulating hormone appeared in the blood stream, yet in women with scanty and infrequent irregular menstruation no hormone was found. This he attributes to the fact that in the latter conditions, the hypoöphorism is merely secondary to decreased activity of the hypophysis. Again he found prolan A in some cases of menorrhagia and severe dysmenorrhœa; this he explained by assuming that the underlying cause of such condition is increased activity of the anterior lobe of the pituitary.

In view of these findings, and in view of the fact that the urine of pregnant animals never gives a positive pregnancy test (prolan B), it is of interest to know whether prolan A is excreted in the urine of castrated animals or not. Kraul[14] found that the hypophyses of rabbits whose ovaries had been removed produced greater prolan A and prolan B effects when transplanted into immature rats than did those from animals not previously castrated.

In the present investigation the ovaries from six rabbits were removed and specimens of urine were subsequently collected in a metabolism cage and tested on immature mice. One of the rabbits died six days after operation, and so cannot be considered in the assessment of the results. Of the remaining five, it was found that two definitely, and a third doubtfully excreted prolan A in the urine. The hormone was present as early as nine days after operation, but in two of the animals it seemed to be only temporary. One of the rabbits had not reached puberty at the time of the operation and it is interesting to note that the pituitary hormone was found in the urine in this case.

The finding of this hypophyseal hormone (prolan A) in the urine of an animal is remarkable: it at least proves that the pituitary of a rabbit is capable of producing it in quantities sufficient to be demonstrable in the urine.

THYROIDECTOMY.

Schilder,[17] in 1911, first showed that histological changes occur in the pituitary in conditions of thyroid aplasia.

Blair Bell,[18] in 1913, described in detail the hypophyseal changes following thyroidectomy in cats, and concluded that "thyroidectomy causes an increase in the secretory activity of all parts of the pituitary body." However, Bryant,[19] although finding an increase in chromophobe cells in the pituitary of the rabbit after thyroidectomy, does not believe that the activity of this gland is increased. It should be noted that, as Blair Bell stated, the thyroid and pituitary of the cat more nearly resemble these organs in the human subject than do those of the rabbit, in which animal experimental changes are less well defined.

Smith[20] showed that ablation of the anterior pituitary leads to atrophy of the thyroid, and that this effect can be prevented by pituitary transplants. Later, Evans and

THE OCCURRENCE OF PITUITARY HORMONES IN THE URINE IN CONDITIONS UNASSOCIATED WITH PREGNANCY.*

BY T. N. A. JEFFCOATE, M.B. LIVERP.,

ETHEL BOYCE FELLOW IN GYNÆCOLOGY AND OBSTETRICS IN THE UNIVERSITY OF LIVERPOOL; GYNÆCOLOGICAL AND OBSTETRIC REGISTRAR, LIVERPOOL ROYAL INFIRMARY.

SINCE the introduction of the Aschheim-Zondek test for pregnancy, many observers have noted that the so-called pituitary hormones may occur in human urine in conditions other than those associated with pregnancy. Prolan A, in particular, has been shown to be present at the menopause, after castration, and in some cases of malignant disease. It might be supposed that such a possibility would affect the accuracy of the Aschheim-Zondek reaction as a test for the presence of living chorionic elements in the body. One must, however, bear in mind the fact that it is the presence of prolan B, and not prolan A, in the urine which gives a positive result —namely, corpora hæmorrhagica and luteinisation in the ovaries of immature mice.

During the past year 250 tests were made on the urines of 169 male and female patients; some of the latter were pregnant, others not; 77 positive and 136 negative reactions were obtained, while in 37 instances the mice died. A considerable number of these experiments were performed with urines from cases of malignant disease, or from women in whom bilateral oöphorectomy had been performed, yet only two errors were made in the diagnosis of the presence or absence of living chorionic elements in the patient concerned. In these two cases the experimental technique, rather than the test itself, was at fault. The percentage error was 0·94 of the tests in which a result was obtained.

There is now no doubt of the value of the test in pregnancy, and in this communication the occurrence of pituitary hormones apart from pregnancy will alone be considered.

Prolan B.

Zondek [1] claims to have obtained A.P.R. II.† and A.P.R. III. in mice injected with urine from two cases of carcinoma cervicis. Elsewhere he states [2] that prolan B may occasionally be found in the urine after a patient has had both ovaries removed. Fluhmann,[3] using the blood-sera of women at the menopause or after castration, sometimes obtained evidence of the presence of this hormone, while Allan and Dickens [4] reported an error in pregnancy diagnosis which arose because the urine from a patient at the menopause produced corpora hæmorrhagica in the test animals. Hannan [5] obtained a positive Aschheim-Zondek reaction in two cases of genital carcinoma, and Stewart [6] reported a similar finding in a case of hyperthyroidism. Recently Susman and Nuttall [7] have claimed that the urines of 14 out of 18 cases of malignant disease produced a positive reaction. If by this they mean that the urines investigated produced the effects of prolan B in the genitalia of mice, it was an unusual finding, for as Zondek's results show, the occurrence of this hormone is rare as compared with the occurrence of prolan A, in these circumstances.

In the face of such evidence, it is not possible to deny that prolan B can occasionally be found in the urine of non-pregnant women. Still in the tests on which this communication is based there has never been any evidence of the presence of the luteinising factor in the urine, except when the patient has had active chorionic elements in the body.

Prolan A.

In that part of the investigation which concerns prolan A, urines from patients at the menopause and after sub-total thyroidectomy were examined. In addition, urines from human beings and animals suffering with malignant disease, or in whom bilateral oöphorectomy had been performed, were tested. The urines, most of which were previously concentrated by a method described by Zondek,[3] were injected by a technique similar to that employed in the ordinary pregnancy diagnosis tests.

MENOPAUSE.

It is generally agreed that at the menopause there is a gradual cessation of ovarian activity, and an associated readjustment of the endocrine balance in the body. In the light of our present knowledge of the relationship between the pituitary and the ovary, it is difficult to be certain whether the diminished ovarian function is a primary or secondary feature of this process. Whatever be the mechanism of the disturbance, the fact that it occurs is evidenced by the excretion of prolan A in the urine. Zondek [5] reports the presence of the follicle-stimulating hormone in the urine of menopausal patients; he is of the opinion that it appears late in this physiological process. Fluhmann [8] found that at the onset of menopausal symptoms, 33 per cent. of all patients have demonstrable quantities of prolan A in the circulation. At a later stage in, or just past, the menopause, he showed that five out of seven patients had this hormone in the blood stream.

The urines of six women who were at, or about the climacteric have been examined; of these, one killed the mice, three contained the hormone, and two did not. Those patients who excreted the hormone were at the commencement of the menopausal disturbance.

Zondek [8] in discussing the reason for the excretion of prolan A at the menopause says that it must be because the ovaries cannot utilise it, or because the functioning ovary normally inhibits the activity of the anterior lobe of the pituitary. He points out that since hypophyseal transplants will stimulate the senile ovary of a mouse or rat, the first view cannot be accepted, and the second must be the true explanation.

CASTRATION.

Fichera,[9] in 1905, first pointed out that hypertrophy of the pituitary follows removal of both ovaries. Blair Bell [10] confirmed this finding, and described microscopical changes which he regarded examined—that is, 14 per cent.—had prolan A in the urine.

---

* This investigation was undertaken on behalf of the Liverpool Medical Research Organisation.

† Anterior pituitary reaction.

A final series of tests were made on rabbits inoculated with the Brown-Pearce tumour. The growth was extensive in each animal whose urine was examined. Altogether, the urines from eight rabbits, the serum from a ninth, and ascitic fluid from a tenth, were tested. In every case a negative result in regard to the presence of prolan A was obtained.

It would seem, therefore, that it is rare to find prolan A in urines of patients suffering with extra-genital carcinoma; only once was it demonstrable in such conditions. On the other hand, its occurrence is common when the malignant disease has its site in the genitalia.

Difficulty is encountered in attempting to explain why malignant tissue should be associated with the excretion of prolan A. It may be:—

1. *That the growth actually manufactures the hormone.*—It is well known that extracts of the human placenta produce in immature mice ovarian responses identical with those which result from the injection of the urine of pregnant women. Moreover, many authorities, including Philipp,[26] Collip,[27] and Bourg [28] are of the opinion that it is the placenta, and not the pituitary, which is the site of origin of the hormones excreted in the urine during pregnancy. If this is true, and since, as Blair Bell [29] has suggested, the behaviour of malignant tissue resembles that of the chorion, then it is reasonable to suppose that the growth may actually produce the hormone. In such circumstances, the individual variation in tumours such as the presence, or absence, of necrosis, or of encapsulation, would explain why the finding of prolan A in the urine is not a constant feature of neoplastic conditions generally. However, even such variations in the tumour do not appear to be sufficient to explain the remarkable fact that the hormone is but rarely found except when the neoplasm is situated in the genitalia. Moreover, in acetone and alcohol extracts which have been made from both human and animal tumours, no hormone has yet been demonstrated.

2. *That the growth may stimulate the pituitary to increased activity.*—In favour of this view, Zondek [1] states that many investigators have found "pregnancy changes" in the hypophyses of patients suffering from malignant neoplasms. More recently, Susman [7] has found histological evidence of increased activity of the anterior lobe of patients dying from these conditions. Berblinger [30] showed that injection of any protein caused pituitary changes, and he considered that in the case of neoplasms the products of tissue necrosis could produce this effect. However, this theory does not account for the fact that in the cases investigated in this series, only *genital* carcinoma caused the excretion of prolan A.

3. *That the increased activity of the anterior pituitary is the cause, and not the result of malignant growths.*—With regard to folliculomata of the ovaries, Blair Bell and Datnow [31] have already suggested that prolan A may be a factor in their ætiology in view of the multiple nature of the primary growths; but regret that they have not had an opportunity of making biological tests in any case of this type. Susman [7] has recently described a treatment for cancer which is based on the theory that the disordered overgrowth of tissues, which occurs in neoplastic conditions, is associated with an increased activity of the anterior lobe, and a decreased activity of the posterior lobe of the hypophysis. However, there is evidence to show that the excretion of prolan A in these cases is the result, and not the cause, of tumour formation. In the two cases of carcinoma corpus uteri which gave positive results, the hormone disappeared from the urine within ten days of hysterectomy. Also, Zondek [1] found that not only did the pituitary hormone vanish from the urine after the removal of the growth, but that it reappeared in the presence of a recurrence.

4. *That the presence of the growth in the genitalia gives rise to impulses which pass from the genitalia to the pituitary.*—It is well known that in the rabbit ovulation occurs about eight hours after coitus. Ovulation is now believed to be dependent on the pituitary, and Fee and Parkes [32] have shown that hypophysectomy, performed immediately after copulation, inhibits the rupture of the follicle in rabbits. It seems, therefore, permissible to assume that the vulva, vagina, and uterus are connected with the pituitary by a hormonal or nervous mechanism. Kraul [14] points out that mechanical irritation of the cervix in animals, or curettage in women, has been shown to produce changes in the ovaries. He states, moreover, that these changes occur even if the ovarian tissue is only present as a graft, and is situated at a distance from the pelvis. From this he infers that the ovarian changes are brought about by the anterior pituitary which is stimulated by impulses, probably nervous in nature, arising in the genitalia. If this be true, it is conceivable that the presence of a growth in the vulva, vagina, or uterus, may act as a local irritant and set up a train of impulses which pass to the pituitary and stimulate it to produce an excess of prolan A. This view will at least explain why prolan A is, for the most part, excreted when the genital tract is the site of the neoplasm. Moreover, the fact that prolan A disappears from the urine after removal of the growth is not incompatible with this theory.

Summary.

1. Experimental results are given confirming the work of other observers who have stated that prolan A can be found in the urine at the menopause after castration, and in some cases of malignant disease.

2. In this series of cases prolan B has never been excreted in the urine except when the patient had living chorionic elements present in the body. In other words, a positive Aschheim-Zondek reaction has never been obtained except in the presence of such elements.

3. It has been shown that prolan A can be detected in the urine of rabbits after castration.

4. Prolan A has also been found in the urine of patients who have had sub-total thyroidectomy performed for exophthalmic goitre.

5. The finding of prolan A in the urine of patients with malignant disease has been almost entirely confined to those cases in which the genital tract was the site of the tumour.

I am indebted to Prof. W. Blair Bell in whose department, and under whose direction, this work has been carried out. My thanks are also due to Dr. M. Datnow for his helpful advice and criticism.

Simpson[21] went so far as to suggest that the anterior lobe of the hypophysis secretes a separate principle whose sole function is to stimulate thyroid activity. Crew and Wiesner[22] have lately produced more evidence in favour of the presence of a separate thyreotropic factor in the pituitary; this they call the "theta factor." Within the last few months Gant,[23] while working with the *Amblystoma jeffersonianum*, has found that heteroplastic anterior pituitary transplants result in an increased activity of the thyroid gland, and that secretion and discharge of the follicular colloid is stimulated. Silverberg[24] has also shown that injections of hypophyseal extracts stimulate the thyroid in guinea-pigs.

The bulk of evidence therefore points to a thyroid-pituitary relationship which is somewhat similar to that of the ovary and the pituitary. Accordingly it was decided to test whether there is any evidence of the excretion of pituitary hormones following removal or reduction of the influences of the thyroid secretion on the body. Total thyroidectomy cannot be performed in the human being, so patients were chosen who had had approximately five-sixths of the gland removed for exophthalmic goitre. This choice was made since it was felt that such patients, more than any others, would be subjected to an immediate reduction of the thryoid secretion in the body.

Out of the nine cases examined, in three definitely, and in two others doubtfully, a hormone whose action was similar to that of prolan A appeared in the urine following the removal of the greater part of an over-active thyroid. It was present as early as the seventh day, but in one case its occurrence was only temporary. Possibly if the whole gland had been removed, all patients, male and female, would have excreted the hormone. Nevertheless, in the consideration of these results, it must be borne in mind that such cases can hardly be comparable with those in which the thyroid is normal ab initio. It would, therefore, be interesting to perform total thyroidectomy on normal animals, especially cats, and to examine their urine subsequently. This was not done in the present inquiry.

Blair Bell[18] demonstrated increased activity of the thyroid following oöphorectomy; it may now be inferred that this effect is only secondary to the pituitary hyperplasia which follows castration. In the same way it is possible to explain the enlargement of the thyroid which sometimes occurs at puberty in patients with hypoöphorism. The increased thyroid activity during pregnancy may be the result of the large amounts of prolan A, or an associated "theta factor" in the circulation, or may be secondary to a diminished ovarian follicular activity at that time. This view is borne out by the work of Riddle[25] who showed that there is a regression in the thyroid of doves during periods of ovarian activity.

From this mass of evidence one arrives at a possible explanation as to why thyroid therapy has been found to be effective in ensuring the continuance of pregnancy to term in those women who have had a series of abortions and premature labours for no obvious reason. The ætiology of these conditions may be related to an increased prolan A, or œstrin, output. In either case, administration of thyroid should tend to inhibit the hypophyseal activity, and to diminish the secretion by it of the follicle-ripening hormone.

DISEASES OF THE ENDOCRINE GLANDS.

It is possible that pathological conditions of the thyroid, suprarenal, and pituitary might, on occasion, result in the appearance of the hypophyseal hormone in the urine. From what has been said, one might expect that in hypothyroidism prolan A would be excreted; no case of this disease was examined. Three patients with exophthalmic goitre gave negative results prior to operation. A case of diabetes insipidus associated with a posterior pituitary tumour likewise had no demonstrable amount of the anterior lobe hormone in the urine. This result, however, is of very little significance since the urine had such a low specific gravity. No prolan A was found in a case of Addison's disease. Lutein cysts of the ovaries have been reported in association with anterior pituitary tumours (Kraul[14]); these may have been due to an excess of prolan B in the circulation. Other observers have found prolan A in acromegaly; in this investigation the urine and blood-serum of one male acromegalic were tested and gave negative results.

NEOPLASMS.

Benign Neoplasms.—Zondek[1] claims to have demonstrated prolan A in the urine of patients with innocent growths. He found that 30 per cent. of patients who had fibromyomata uteri excreted the hormone, but in no cases of innocent ovarian tumours did he obtain a positive result. I have investigated six patients with fibromyomata uteri and in none was there any evidence of prolan A in the urine. Three cases of ovarian cyst (one dermoid, two cystadenomata) also gave negative results.

Malignant Neoplasms.—Zondek[1] found that in about 80 per cent. of female patients with genital carcinoma prolan A was excreted in the urine. It occurred in amounts as great as 200 R.U. per litre. In cases of extragenital carcinoma, the percentage of positive results was only 36. He also maintains that the presence of the hormone had no relation to the age of the patient, and was not associated with the menopause. Moreover, it was not related to the type of tumour.

In the present investigation the hormonic content of the urine of male and female patients suffering from malignant neoplasms in various parts of the body were investigated. It was found that such urines are exceptionally toxic to the mice. The clinical diagnosis was always confirmed at operation or post mortem.

Of three cases of genital carcinoma in males in which a result was obtained, one definitely had prolan A in the urine, and another probably had small amounts. It would be of interest to investigate a case of so-called chorion-epithelioma of the testis, but no such case has come under notice since this investigation was begun. A result was obtained in ten cases of extragenital carcinoma in males and in none was there any evidence of the pituitary hormone.

Zondek found that 13 per cent. of male patients with malignant disease gave a positive test for prolan A. Taking both of my series together, two out of thirteen patients excreted the hormone in the urine—that is, 15·4 per cent.

Zondek demonstrated prolan A in the urine in almost all cases of genital carcinoma in females. He said that the urines from:

82·5	per cent. cases of	*carcinoma cervicis*	gave positive results.
75·0		carcinoma corpus uteri	
75·0		ovarian carcinoma	
100·0		epithelioma vulvæ	

In the present investigation, 24 tests were made on the urines of 17 patients. In seven of these tests the mice died. The results summarised show that in:

Carcinoma cervicis	16·6	per cent. excreted prolan A.
" corpus uteri ..	66·6	" " "
" vaginæ	75·0	" " "
" vulvæ	50·0	" " "

Of the female patients suffering from extragenital carcinoma and sarcoma, only one out of seven given. Before retiring for the night, such patients as have a history of nervousness or insomnia usually receive luminal or veronal by mouth, to ensure a good night's rest. Cases of diabetes are given insulin just before operation, but even this may be omitted if the case be mild. If chronic pyloric obstruction with cachexia be present, or hypotonia, an injection of pituitary extract just before operation is indicated.

A routine measure in all major operations is the use of morphine or its derivatives. Prof. Finsterer employs omnopon, 0·02 g. one hour before operation, and immediately before 0·015 to 0·02 g. of morphia with 0·0005 g. of atropine. The main purpose of these drugs is to allay apprehension on the part of the patient rather than to utilise their anodynic powers.

During operation.—It is usual to begin the operation by block anæsthesia of the anterior abdominal wall[8] with 0·5 per cent. novocain-adrenalin solution. This is injected through the skin and into the subcutaneous tissues below the proposed site of incision and directly into the recti abdominis. To ensure proper relaxation, 60 to 80 c.cm. of the anæsthetic are used, mostly put into the substance of the muscle. This is carried through to the peritoneum. When the peritoneum has been incised, it is held up by sharp retractors and infiltrated from the inside with 10 to 15 c.cm. of the anæsthetic, on either side of the incision. If this be injected away from the mid-line, it will permit of subsequent painless pulling on retractors, to disclose the field of operation.

The index-finger of the left hand is now introduced immediately below the liver and downwards between the viscera, to the region of the twelfth thoracic vertebra. Here the pulsating aorta is readily felt, and the finger is next pushed slightly upwards until the pulsating hepatic artery is encountered. By firm pressure with the finger-tip, the aorta and vena cava are then pushed apart and a fine needle, 20 cm. long, is guided, above the finger, right down against the bone. Slowly, with repeated aspirations to be sure the needle point is not in a vein, about 50 to 70 c.cm. of the 0·5 per cent. solution are now injected. This is the method of Braun.[9] If blood be aspirated, even in the slightest amount, the needle is immediately withdrawn and mesenteric (root) anæsthesia substituted. The reason for this is that the fluid may be forced through even minute openings in the veins, the result being rapid intoxication. In anæmic and cachectic individuals, only 50 c.cm. of 0·25 per cent. solution are used.

The anæsthetic is usually effective in ten minutes, and lasts from three-quarters of an hour to two hours. In gastric resections the preparation of the duodenum and pancreas is usually completed in one hour, and after that any pain experienced is usually not intense. Nausea and vomiting due to peritoneal irritation, to too rapid absorption of the anæsthetic or, possibly, to the morphia previously given, may occur, but are usually overcome by simply lowering the head. If this be insufficient a hypodermic of caffeine sodium benzoate is generally adequate.

In a publication in 1926 Prof. Finsterer [10] reported 807 cases of major abdominal operation under local anæsthesia as performed by Braun's method. In this series, ether was used only 71 times (8·8 per cent. of cases). Of 468 resections of the stomach reported up to this time, ether was used 33 times (7 per cent. of cases). Those requiring ether received varying amounts of the anæsthetic up to 50 c.cm.

Sometimes ether is essential, as in nervous children, or cases of diffuse peritonitis following perforation of a viscus, where the peritoneum must be swabbed and the mesentery mopped up. Some severe operations, lasting up to five hours, will frequently require ether in the terminal stages, as the effect of the local anæsthetic is not lasting.

AFTER-TREATMENT.

Immediately after operation the patient is put in a partial Trendelenburg position,[11] with the knees elevated in order to prevent thrombosis of the leg veins, dangerous on account of lung embolism. The shoulders are raised so that the patient assumes a partial sitting position, in order to prevent lung congestion.

Where there is cause to fear the onset of post-operative lung conditions, as in overworked labourers or aged individuals with extensive emphysema, it is usual to give transpulmin, a quinine derivative, twice daily, to prevent pneumonia. All patients over 60 receive injections of 2 c.cm. of camphorated oil every two hours for three days to aid expectoration. So many aged individuals have a purulent bronchitis with impaired ability to bring up foul sputum that it has proved decidedly advantageous to take particular care of them after operation. Although all patients receive one injection of pantopon the first night after operation (unless contra-indicated through old age or severe anæmia), the injection is not repeated. It is felt that drugs of this nature tend to inhibit the cough reflex, and in this way to encourage retention of lung secretions. The older patients are encouraged to breathe deeply at all times, and to cough occasionally. When they cough an attendant should support the recti abdominis so that no pain is experienced, and damage to fresh sutures is minimised.

Nausea and vomiting within the first 24 hours after operation are usually due to previously administered morphine or to foul blood in the stomach. The latter should be removed by gastric lavage. Where post-operative hæmatemesis occurs the stomach is immediately washed out with iced water and the manœuvre repeated until the return flow is clear. If at the end of several washings blood is still present, it is best to wash with 100 c.cm. of a 1 in 1000 solution of silver nitrate, a procedure which may be repeated once.

There have been no deaths from operative shock, and no deaths from heart failure, although many of the cases were considered hopeless by other surgeons and were refused operation by them. This fact is attributed to exclusion of deep general narcosis and to efficient after-treatment. It has been observed, in the vast majority of cases, that the general condition of the patient is better and that meteorism and nausea and vomiting are much less than after the use of general anæsthesia.

Only three cases of acute dilatation of the stomach have been met with by Prof. Finsterer in all his cases done under local anæsthesia (over 3600 laparotomies), and these were attributed to chilling of the organs, due to the fact that the operations were performed in cold rooms (war period). They rapidly recovered on stomach lavage.

For post-operative pains from excessive gas-formation, it is usual to give hot air treatment over the abdomen by an arc of electric lights. Pantopon serves only to increase the constipation. The rare cases of severe intestinal atony encountered after the use of local anæsthesia have never proved fatal. They are treated by enemata on the second day, when gas and a small amount of fæces usually pass, and thereafter no treatment is required. In contrast to this are 600 cases done under general anæsthesia by Prof.

OPERATION UNDER LOCAL ANÆSTHESIA:

PREPARATION AND CARE OF THE PATIENT.

BY WILLIAM MOFFATT, M.D. MONTREAL,

OF THE ROYAL VICTORIA HOSPITAL, MONTREAL; LATE ASSISTANT TO PROF. HANS FINSTERER, VIENNA.

DURING the past 75 years the progress of surgery has been intimately connected with the more or less thorough exploitation of the use of general anæsthetics. As actual preventives of pain, no drugs have, as yet, been discovered which can surpass them in this particular field. And yet their effect on pathological conditions of certain vital organs of the body, such as the heart in myocarditis, the lungs in caseous tuberculosis, and the kidneys in the various forms of nephritis prevent their use in countless numbers of people.

In order to eliminate diseased conditions where a general anæsthetic is to be employed, it is necessary to perform certain examinations and tests on the patient. Usually the first approach is the general physical examination of all the systems of the body, with particular emphasis on the condition of the heart and the blood pressure, and a thorough inspection of the lungs. Where the general survey of the patient leaves any doubt as to the functional ability of any of the main organs, the careful surgeon will demand, on certain of his cases, electrocardiograms, basal metabolic determinations, chest radiograms, or kidney function tests. Even urine cultures are frequently demanded. Urea-concentration tests are desirable also, for it has recently been shown by Haines and Milliken[1] (also F. Stephen[2] and J. Minnit[3]) that in prolonged ether-anæsthesia the excretion of the anæsthetic by the kidney actually causes a tubular degeneration, with partial disintegration of the epithelial cells and consequent post-operative rise of blood chemistry values. Hæmoglobin valuations, erythrocyte counts, and blood groupings are regarded as more or less routine measures in all the severer operations.

Abel[4 5] has recently advocated as immediate pre-operative requisites the following measures: at least two days' complete rest in bed; glucose given as barley sugar or orange juice, to keep up carbohydrate metabolism in order to fight off tissue insult; a sedative hyoscine possibly to be preferred the night before operation to ensure good sleep; blood transfusion if the hæmoglobin determination be below 50 per cent., or if the erythrocyte count be lower than 4,000,000 per c.mm.; glucose and insulin pre-operatively in cases of diabetes; and in the hæmorrhagic states, such as icterus or hæmophilia, 10 c.cm. of 10 per cent. calcium chloride intravenously combined with 15 units of parathyroid extract.

Lambret,[6 7] before the French Surgeons' Congress in October, 1930, recommended a simple diet before operation consisting of plenty of fruit and vegetables, very little meat, and no alcohol; thorough evacuation of the intestines should be accomplished by means of enemata, but aperients should be discouraged; if the urea content of the blood be over 0·5 g. operation is to be avoided, while in decompensated cardiac cases only urgent operations should be permitted; in chronic alcoholism alcohol and opium are given before operation to prevent delirium.

Neumann (Brussels) requires that his patients rest in bed before operation, and he gives them plenty of fruit juices, and infusions of physiological saline; for the last five days before operation, only a milk diet is permitted. De Fourmestraux emphasises the importance of oral and dental treatment which, if neglected, might lead to pneumonia. Pauchet prepares obese patients for operation by ordering complete rest in bed for a week, and giving them only a fruit and lemonade diet. Rowntree[4] even goes so far as to advocate a special pre-operative ward, to contain beds in charge of a physician well acquainted with surgical risks.

The trouble and expense involved in all these procedures appear essential in the preparation of cases for general anæsthesia. However, by introducing local anæsthesia into the field of major surgery, a large number of the surgeons of Continental Europe have, in one move, almost entirely eliminated these procedures. In the hands of English-speaking surgeons, the potentialities of local anæsthesia have never been thoroughly exploited. We may arrive at some idea of the economy of both labour and expense by a perusal of the experience of Prof. Finsterer of Vienna in his work with local anæsthesia during the past 20 years.

A TYPICAL OPERATION UNDER LOCAL ANÆSTHESIA.

If we choose as a typical major abdominal operation that of gastric resection[8] for duodenal or gastric ulcer, we may better visualise the procedure involved in caring for the patient. This operation requires from 1½ to 2½ hours, and in suitable cases is done entirely under local anæsthesia.

Before operation.—No condition of the heart, kidneys, or lungs contra-indicates operation. Hence accessory aids to diagnosis, such as electrocardiograms, chest radiograms, blood chemistry valuations, and kidney function tests, are all eliminated. Once the diagnosis of duodenal or gastric ulcer has been decided upon,* and operation deemed essential, other details of physical examination of systems outside the gastro-intestinal tract are of secondary importance. Only obvious factors which would contra-indicate major operation under general anæsthesia are taken into consideration. Examples are: extremes of anæmia, obvious by the pallor, where the hæmoglobin determination is below 25 per cent. or where the erythrocyte count falls below 2,000,000 per c.mm. In such cases it is found that the patient shows better recuperative powers if treatment be given after operation. It is usual, therefore, to transfuse such patients with 500 c.cm. of blood immediately post-operatively. Jaundice and cases of known blood dyscrasia are usually treated before operation. Icterus subjects receive one-third of an erythema dose of X rays over the spleen within four hours before operation. Beyond this time, e.g., in one case of Prof. Finsterer's where X rays had been given 20 hours before operation, there is extremely little bleeding to be seen during operation from cut vessels, with obvious difficulty in ligating; the danger of post-operative hæmorrhage in such cases is, of course, great. In addition, such cases of jaundice receive calcium chloride or horse serum intravenously before operation. When post-operative bleeding is suspected, these patients receive blood transfusions.

It is usual to ask the patient to arrive at the hospital the night before operation. No period of rest or building-up is required; nor is glucose deemed necessary to fight off the effects of tissue damage. An aperient of magnesium sulphate or castor oil is

---

* The usual methods in arriving at this diagnosis are, of course, employed, i.e., history, physical examination, gastric analysis, fluoroscopy and X ray, stool analysis, &c.

The amount of fluid which should be withdrawn is generally regarded as being the maximum that can be obtained. There is little doubt that this is the correct procedure in the acute stage of the disease. As Krasnogurski pointed out, the decrease of the pressure in the ventricular system is the natural incentive to the flow of cerebro-spinal fluid and this is of great value in treatment, since the child absorbs a good deal of cerebro-spinal fluid. When, however, the acute stage of the disease is over and the patient is still secreting an abnormal quantity of cerebro-spinal fluid, the question arises whether the withdrawal of the maximum quantity of fluid is the best method of treatment as possibly a greater stimulus to further secretion might be given than is desirable. This possibility was borne in mind in the treatment of the following case.

Of four cases of cerebro-spinal meningitis admitted last ear to the Ilford Isolation Hospital three recovered. The rst three were all of the toxic variety with purpuric rashes nd were all due to type I. meningococcus. The first of these was treated with an antimeningococcal serum probably eficient in anti-endotoxic action, for it had no specific ffect and the patient died. The next two cases were reated with another brand of serum which had an immediate nd specific effect; both patients recovered with great apidity.

The fourth case, a boy aged 8 years, was admitted to hospital with a history of influenza for 14 days with omiting, headache and cough, pains in the limbs, and nasal ischarge two days before admission. When admitted he as conscious, with flushed cheeks, marked head retraction, Kernig's sign + both sides, retracted abdomen, T. 101·4°, . 84, R. 22. Lumbar puncture was performed and 25 c.cm. f turbid fluid were withdrawn. The report on the fluid howed no sugar, albumin +, pus cells, and meningococci nagglutinable to type sera I., II., III., and IV. Five c.cm. f antimeningococcal serum were given intramuscularly in desensitising doses commencing with 0·1 c.cm.; finally 5 c.cm. of antimeningococcal serum were given intrathecally.

During the next ten days lumbar puncture was performed aily and a total of 120 c.cm. of antimeningococcal serum as given intrathecally and 55 c.cm. intramuscularly. After he first punctures a general anæsthetic was given not only ith a view to the comfort of the patient, but as pointed ut by Flack [5] the amount of fluid can be increased by this means.

At the end of this period the fluid still showed many polymorphonuclear cells with many intracellular meningococci. It would appear that the serum had little if any specific action in this case. The temperature from admission to March 10th was remittent in character; from March 11th to the 15th it was intermittent. It remained subnormal from March 23rd to April 3rd. The fluid on March 24th was clear and sugar was present in it on March 27th. On March 31st 10 c.cm. of clear fluid only were removed, pparently not under pressure.

Lumbar puncture, which had been continued daily, was iscontinued for the first three days in April. This was followed by a relapse; the temperature rose to 103°; the patient had headache and vomited. The lumbar puncture which was performed showed fluid under pressure and 35 c.cm. f clear fluid were removed. Lumbar puncture was continued daily; the temperature fell, it remained a little unsettled or two days. On April 10th he had another relapse; he vomited and his temperature was raised to 103° and remained above normal for three days. The cerebro-spinal fluid was still under pressure. It was decided to estimate the pressure of the cerebro-spinal fluid by a Greenfield's manometer and only to remove a sufficient quantity of fluid to reduce it to normal.

The estimations were commenced on April 29th. On his day the pressure was 300 mm. The process was repeated daily for 21 days. On May 1st the fluid showed no polymorphonuclear cells, no meningococci, protein slight trace, globulin absent, sugar normal.

The boy's condition slowly returned to normal. The pressure of the fluid remained high, but on May 29th the withdrawal of 18 c.cm. of fluid was sufficient to reduce it to normal. Lumbar puncture was discontinued on this date. On June 9th his temperature rose again and as the Kernig was still +, lumbar puncture was done. Only 10 c.cm. of normal clear fluid not under pressure were removed; the fluid showed no meningococci and no excess of protein. The cause of the rise in temperature was a myalgia.

From this date onwards no further lumbar punctures were performed and the boy made an uninterrupted recovery and was discharged on June 27th after a period of over 17 weeks in hospital, 78 lumbar punctures having been performed, and a total of 2601 c.cm. of cerebro-spinal fluid having been removed. After a period at a convalescent home he returned to school and is normal in health both physically and mentally.

The interesting points in the case are: (1) the length of time during which the cerebro-spinal fluid was secreted in excess amount, two "relapses" occurring; (2) the large number of lumbar punctures required (78) to effect a cure; (3) the importance of this treatment in view of the aberrant form of meningococcus found, the poor specificity of the serum as well as the continued high pressure of the cerebro-spinal fluid; (4) the attempt made to lessen the effect of overstimulation of the secretion of cerebro-spinal fluid by measuring the pressure and withdrawing sufficient only, when the fluid became clear, to bring the pressure to normal.

A CASE OF ACUTE ANÆMIA DURING PREGNANCY.

BY D. H. MACLEOD, M.S. LOND., F.R.C.S. ENG.,
GYNÆCOLOGICAL AND OBSTETRIC REGISTRAR TO THE MIDDLESEX HOSPITAL;
AND
ALEXANDER WILSON, M.D. ABERD.

WE think this remarkable case is worthy of record as an example of a rare form of pregnancy toxæmia which has very seldom been reported in England.

The patient, a well-nourished woman of 25, was first seen in private practice on Nov. 9th, 1931. She had had one child, born uneventfully sixteen months before, and she was now pregnant again, about seven months according to her own calculations. She had not felt well since the onset of the pregnancy and she complained of a "cold and cough."

She looked very ill. The temperature was normal and the pulse-rate 110. There was marked anæmia, as shown by the extreme pallor of the lips and conjunctivæ, and there was extensive œdema involving the face, upper and lower extremities, and, to a lesser degree, the abdomen and back. A systolic murmur was audible over the præcordium but the lungs appeared normal. The throat was much injected and this undoubtedly was responsible for her cough. She was a heavy smoker. The duration of pregnancy, as judged by the height of the fundus uteri above the symphysis pubis, was little more than six months. Fœtal parts could be felt and the fœtal heart was heard. The urine was clear and the specific gravity was 1025. Apart from a slight trace of albumin there was no other abnormal constituent present.

Eliminative treatment was instituted and the patient put on a fluid diet. Definite improvement followed and by the fourth day there was marked diminution in the œdema but the pallor remained. On the fifth day she became suddenly worse, with pain in the back and legs, and great breathlessness. She was immediately sent to the Middlesex Hospital.

She was admitted at 8.40 P.M. on Nov. 15th, and seen by Mr. Frederick Roques. She was profoundly anæmic and the pupils were widely dilated and reactive to light. The pulse was running in character and individual beats could not be felt. The temperature was 96·5° and the respiration was rapid, about 50 to the minute. Air-hunger

Finsterer where two proved deaths from atony of the gut were observed, and three probable fatalities. In cases of chronic constipation or morphine addiction, where drugs are required post-operatively, meteorism is combated by warm air applied to the abdomen, washing out of intestines with warm water at 40° C. and injections of pituitary extract two or three times daily.

It is believed that these post-operative precautions avoid complications. In 1312 cases of gastric resection for gastric or duodenal ulcer (up to 1930) there have been only three deaths from pneumonia and two cases of pulmonary embolism.

Apart from these measures against specific disorders, general principles are followed, which aim at the general building-up of the body resistance. For the first 24 hours the patients receive only fluid, in the form of a Murphy drip, either saline or 5 per cent. glucose. In the next 24 hours they have a tablespoonful of alkaline mineral water, or cold tea by the mouth every hour. If there be no vomiting after 48 hours, they receive tea with small amounts of milk, in gradually increasing doses. After the fourth day the diet becomes semi-liquid, consisting of gruels, purées, mashed potatoes, thin cream of wheat, honey, and tea with milk. At the end of about the second week, finely ground-up meat is added. The post-operative diet in cases of duodenal ulcer is very strict, as there usually remains a chronic gastritis which must be given time to heal.

RESULTS.

The results obtained in the employment of the measures outlined above in the hands of proficient English-speaking[12] surgeons should coincide closely with those of surgeons of continental Europe. Certainly the statistics of Prof. Finsterer in his large series of cases appear amply to justify the routine adoption of local anæsthesia in all major abdominal surgery.

Follow-up statistics of resection for gastric ulcer[13] from 1911 to 1923 show 105 cases, with complete cure in 98 per cent. There were no dietary limitations, all gained in weight, and all were able to do hard work. Two of the cases complained of heartburn and eructations when they ate certain foods. Of 236 resections for duodenal ulcer performed from 1916 to 1923, 94 per cent. have been cured. Only one case of proved jejunal ulcer was demonstrated after gastric resection, and this was cured by reoperation with a more extensive removal of the stomach remnant. It is believed that good end-results ensue only when a large part of the stomach has been removed and retrograde filling prevented by attaching the afferent loop high up on the lesser curvature.

One criticism of this operation (von Haberer) is that full meals cannot be taken because such small stomach remnants are left. Symptoms in such cases are palpitation, dyspnœa, fullness and nausea. This may occur in the first few weeks following the operation, but if the patient lies down for ten minutes after each meal, such symptoms rapidly disappear. After two to three months the jejunal loop shows immense compensatory enlargement, so that after that time full-sized meals may be taken without discomfort. It must be emphasised that moderation in diet is essential for two or three months, but after that the patient may eat any food. Opposite to this is Moynihan's advice after gastroenterostomy, where he advocates careful dieting at all times.

Arthur Hurst[14] indicates the danger of diarrhœa following resection of the stomach. The probable cause would be inability of the acid barrier of the stomach to cope with pathogenic micro-organisms from the mouth, so that enteritis or colitis may arise. Up to the present time Prof. Finsterer has had only two cases of diarrhœa following all his resections, and the condition was present only when the patient ate certain foods. As to whether or not micro-organisms may readily pass through such a stomach where so little acid is present, later to penetrate bile-ducts, pancreatic ducts, or invade the gut wall to serve as foci of chronic infection—there is no evidence to show any greater incidence of long-standing sepsis among those with stomach resection than among ordinary individuals.

Only one, doubtful, case of pernicious anæmia following resection has been seen in Prof. Finsterer's cases. Here the internists said the blood picture and the symptoms were not those of true pernicious anæmia, while the pathologist claimed that the bone-marrow picture was typical of Addisonian anæmia.

The efficacy of splanchnic anæsthesia to inhibit pain in major abdominal surgery appears to be well established. The writer has observed many cases fall into a peaceful slumber during the course of the operation. From a purely mercenary point of view, it appears essential for the larger hospitals to dispense with the use of general anæsthesia whenever possible and to substitute local anæsthesia. Finally, when one sees patients who have had the stomach resected the previous day sitting up in bed reading, or asking why they are not permitted real meals to appease their hunger, one wonders if local anæsthesia should not be more universally employed from a purely humanitarian point of view.

Clinical and Laboratory Notes

A CASE OF CEREBRO-SPINAL FEVER.

RECOVERY AFTER SEVENTY-EIGHT LUMBAR PUNCTURES.

BY A. H. G. BURTON, M.D. LOND., D.P.H.,
MEDICAL OFFICER OF HEALTH, ILFORD.

ONE of the difficulties occasionally experienced in treating cases of cerebro-spinal fever is the continued increased secretion of cerebro-spinal fluid, which may go on during convalescence. Foster and Gaskell[1] have described a case in which the illness ran a prolonged course of over two months, 32 punctures in all being performed; the condition in this case, clinically, was such as to give rise to the fear of hydrocephalus and on this hypothesis lumbar puncture was vigorously persevered with and the patient recovered completely. The importance of repeated lumbar puncture is well recognised. It was emphasised in 1905 by Lenhartz,[2] who pointed out the desirability of measuring the pressure of the fluid, and of not removing more than 50 c.cm. at one puncture. Neale[3] has also commented on the importance of lumbar puncture for the relief of pressure during convalescence and in three of her cases 20, 10, and 17 lumbar punctures were carried out. Krasnogurski[4] has treated cases of suppurative meningitis with increased pressure and compression phenomena by temporary spinal drainage by means of a thin silver tube.

He lay quiet and lethargic for four days, incontinent f urine and fæces, and masturbating openly and frequently. le then became less drowsy and would speak willingly, ith a dull smile. He tended to be fatuous in his replies, ying he had been sent here by some fool, and was really s well as anybody. Now and then he would sing loudly. he left pupil was now larger than the right, and there were apid nystagmoid movements of both eyes on looking to the ght. The tendon reflexes of his right arm were more active an those of the left. Five days after admission he was ized with hiccough which lasted for half an hour. He as transferred to King's College Hospital a week after dmission, under the care of Dr. Kinnier Wilson, and his ondition is at time of writing, 14 days later, in all essentials nchanged save that he is now orientated for time and place. e has no memory of having been admitted to the Maudsley ospital and says that he was taken to the ward in which e now lies because he had pneumonia.

It will be seen that both these patients presented ymptoms *suggestive of an encephalitis*. There was o evidence that this was a secondary encephalitis ccurring in connexion with disease of the meninges r with a local or general systemic infection. Neither as there evidence that it was a primary encephalitis ssociated with poliomyelitis. When it is considered at both patients became lethargic during a febrile ttack and showed a lymphocytosis and an increase f protein in the C.-S.F., while one patient had iccough and the other a disorder of sleep-rhythm, ese facts, together with the neurological findings escribed above, appear to make the diagnosis of cute epidemic encephalitis a probable one. Again, e patients manifested the form of mental disorder hich may be seen in toxic-confusional states (where, s is known the form of memory disturbance characteristic of the Korsakow symptom-complex may occur), nd for such a toxic-confusional state no other cause ould be found.

Even had there not been the findings described it of interest that Delater and Rouquier[1] describe ow a patient of theirs became disorientated in time nd space after a febrile attack, presented no physical gns, and was found to show the changes characteristic of encephalitis lethargica in his brain at autopsy, hile Kirby and Davis[2] in a review of the subject ress that during an epidemic of encephalitis many ases of acute psychosis are *not* recognised until ost-mortem as having been cases of this disease.

The most common mental manifestations of acute pidemic encephalitis described in the literature are a omnolence deepening into stupor and a restless isorientation with hallucinations. Catatonic maniestations have been frequently observed. Though are, the occurrence of the memory disturbance haracteristic of the Korsakow symptom-complex is lescribed by Kirby and Davis[2] and by Abrahamson,[3] while Hesnard[4] speaks of definite "Formes Korsaowiennes" in acute encephalitis making the important oint that the true Korsakow syndrome is not nanifested in that the patient does not show peripheral euritis. Climensko[5] gives the case-history of one of is patients who was brought to him as "not right in is mind." He had a history of diplopia and of high emperature, and when seen had ptosis. This patient, who confabulated freely, made a good recovery in four weeks.

The excellent recovery made by the first of the two cases described, who left the Maudsley Hospital with no evidence of intellectual deterioration, despite having manifested mental symptoms of a gross organic kind six months before, appears to be in no way unusual. Kirby and Davis[2] were unable to find evidence of organic mental impairment in the great majority of their cases on discharge.

Had the two cases described occurred at a time when many cases of acute epidemic encephalitis were being reported, as for instance in 1918, their chief interest would have lain in the type of mental disorder manifested. To-day they raise the question as to whether similar cases are occurring at the present time, toxic-infective mental states which as has been said show few or no physical signs of organic involvement and tend to make a good recovery. It will be of interest to follow the after-history of these two patients, as the development of the familiar sequelæ of lethargic encephalitis would confirm the diagnosis.

I am grateful to Dr. E. Mapother, medical superintendent of the Maudsley Hospital, for permission to publish these cases, and to Dr. A. C. D. Firth and Dr. Kinnier Wilson for their kindness in allowing me to make mention of the progress of these patients while in King's College Hospital.

NEW INVENTIONS

BRONCHOSCOPIC APPARATUS.

In *a recent paper*[1] we *mentioned* that we would shortly publish a description of a bronchoscope and accessories which we have had constructed for our special work in diagnosis and treatment. We found that the existing instruments each of them failed in one direction. The Haslinger bronchoscope, whilst giving ideal forward illumination with a clear vision to the terminal branches of the lower lobe bronchi, was unsatisfactory in cases of bronchiectasis and abscess, since no arrangement for drainage could be adequately added; the pus coughed out on introduction not only incommoded the operator, but obscured the mirror, rendering further observation difficult. The Jackson instrument, whilst giving adequate drainage, failed in its lighting capacity; the illumination is local and in looking down the bronchial tree one had to look through the globe of light and got very poor illumination beyond. In addition to this the Jackson instrument on account of this defect in lighting was not satisfactory for use with a telescope, neither could a telescope be conveniently adapted to the Haslinger.

The use of a telescope has not been favoured by laryngologists generally, but we may point out that without this aid vision can only be continued in parallel lines corresponding to the bore of the tube, the object to be viewed must be brought into this comparatively small area, vision up the branch bronchi is almost impossible except by excessive manipulation of the tube. By placing one's eye at the *distal* end instead of the proximal—by means of a lens—a wide view angle is obtained so that it is possible to see well up the openings; moreover, a truer view of the colour and condition of the mucous membrane is obtained. By use of a retrograde telescope a view up the upper lobe bronchus can be obtained so that the terminal branches may be examined; we imagine that we are the first to have had this view of the upper lobe bronchus and its branches in the natural position.

The new bronchoscope resembles the well-known Chevalier Jackson instrument in general appearance. The shape was marked and she was very restless. The heart was enlarged and the heart sounds clear but weak; adventitious sounds were not heard. The blood pressure was 120 mm. Hg. Moist râles could be heard all over both lungs. The abdomen was soft and the liver and spleen could not be felt. She did not complain of any abdominal pain or tenderness. The fundus uteri was at the level of the umbilicus and fœtal parts were readily felt but the fœtal heart could not be heard. The cervix was dilated to two fingers and there was no external hæmorrhage. There was a slight trace of albumin in the urine.

---

[1] THE LANCET, Jan. 30th, p. 224.

The patient thus presented an almost typical picture of a severe internal hæmorrhage, save for the absence of abdominal signs and she was taken to the theatre, but died before the abdomen could be opened.

A post-mortem examination was performed by Sir Bernard Spilsbury and the findings were as follows:—

The heart was dilated and showed extensive fatty degeneration of its muscle. The lungs were very œdematous and the liver and spleen were only slightly enlarged. Histological examination of the liver showed the presence of free iron and some fatty degeneration of the liver cells. The kidneys were normal apart from some slight swelling of the cortex and the ureters were both somewhat dilated. The uterus contained a complete and unruptured gestation sac and the placenta was normal and not detached. The fœtus was well developed and weighed 3 lb. The cervix admitted three fingers.

Sir Bernard Spilsbury expressed his opinion that death was due to severe anæmia, but that the cause of the anæmia was obscure. Unfortunately the patient's condition precluded an examination of the blood before death nor was the bone-marrow examined afterwards; but the probability is that the condition was due to the presence in the blood of some toxin derived from the pregnancy which produced acute destruction of the blood corpuscles and inhibited blood formation.

Our reason for placing on record a case so incomplete in regard to laboratory detail is to emphasise the necessity for carrying out simple hæmatological investigations as a part of good antenatal work.

We are greatly indebted to Sir Bernard Spilsbury for his report.

ACUTE ENCEPHALITIS AND THE KORSAKOW SYMPTOM-COMPLEX.

By C. Clifford Davis, M.B., M.R.C.P. Lond.,
ASSISTANT MEDICAL OFFICER, THE MAUDSLEY HOSPITAL, DENMARK HILL, LONDON.

The two cases described are of interest in that they both occurred within the last six months of 1931 and that both patients were disorientated and manifested the memory disorder characteristic of the Korsakow symptom-complex together with a history and clinical and laboratory findings strongly suggestive of acute epidemic encephalitis.

Case 1.—The first patient, a single woman of 54, was admitted to the Maudsley Hospital from King's College Hospital in August of last year with a history that she had taken to her bed five weeks before with a sudden pain in the back of her head and a temperature of 103°. This pyrexia continued for some days. Prior to her admission to hospital her temperature had begun to rise at night. By night she was wakeful and restless, by day she was drowsy. Her body muscles twitched, and she was obstinately constipated.

On admission to King's College Hospital, three weeks after her illness began, she became afebrile. Her abdominal reflexes were absent and both plantar responses were extensor. She is reported to have shown a transient diplopia on the day of her admission. Her memory for recent events was poor and she remained restless at night. The cerebro-spinal fluid (C.-S.F.) contained 20 lymphocytes per c.mm. and 275 mg. of protein per 100 c.cm. Chlorides were not diminished, sugar was normal, neither tubercle bacilli nor other organisms were found, and the fluid was sterile on culture. The Wassermann reaction of her blood and C.-S.F. was negative.

On admission to the Maudsley Hospital she lay with her head flexed off the pillow and her eyes closed. When asked to open her eyes she would do so, and having replied to a few questions in a dull, slurring, expressionless voice she would quickly close them again. Her face was pale and wasted and her expression vacant and apathetic. Her left pupil was larger than her right and both were dilated, her abdominal reflexes were absent, and she had a left extensor plantar response. The muscles of her neck, thorax, and abdomen showed a quiet myoclonic twitching. There was no evidence of meningeal involvement. In the C.-S.F. the lymphocytes had fallen to 16 per c.mm. The protein was now 57·5 mg. and the Lange curve 4 4 4 4 3 2 1 1 0 0. There were no abnormal findings in her urine and the blood-urea was 13·8 mg. There was no agglutination to organisms of the typhoid-paratyphoid group.

Seen within ten minutes of entering the ward she had no memory of her journey, believing herself to be in her bed at King's College Hospital. She was also disorientated for time, and perseverated in her replies. She was not aphasic, and recognised common objects. She was slow, clumsy, and hesitant in her movements. Seen an hour later she believed herself to be in the Weir Hospital, Streatham, and had no memory of having seen me before. As night fell she became restless, and made repeated attempts to leave her bed.

There was little change in her condition till four days later, when she sat up in bed with flushed face and told me of her long walk to the hospital the night before, and of how she had helped herself along with a stick. She greeted a patient who sat near her bed as an old friend from Southampton, and commented sympathetically on the change in her appearance. She failed grossly in simple calculations, and was unable to repeat simple stories. Her manner was cheerful and pleasant, at night she remained restless. There was no change in her physical signs. She was incontinent of urine and fæces for her first ten days in hospital.

Fourteen days after admission the left pupil remained larger than the right, and the abdominal reflexes absent. Plantar simulation no longer evoked an extensor response. Her disorientation persisted and she continued to manifest the memory disorder characteristic of the Korsakow symptom-complex, greeting me as her family physician and describing how I had first seen her in the drawing-room of her own house.

The patient now began to make slow but steady progress, gaining weight and occupying herself quietly with knitting. Her memory defect gradually cleared up, and within three months of her admission she was correctly orientated in space and time. At no time had there been evidence of hallucinations.

Upon her discharge six months after her illness began, she was in good physical health and presented no physical signs suggestive of organic nervous disease. There was no evidence of recent memory defect, there was no confabulation, she was able to perform calculations accurately, and in general presented the picture of a quiet, pleasant, educated woman. It is hoped to keep in touch with her in the out-patient department.

Case 2.—A boy of 16 was admitted to the Maudsley Hospital in January of this year. Four weeks before he had complained of feeling ill and drowsy, and was thought to have had a cold. His temperature was 100°. He remained drowsy for a week, and his parents describe him as having then become "peculiar" and "delirious." His temperature was 100° on the evening before he came into hospital.

On admission he lay quietly in bed with his eyes shut. Asked to open them he would do so, look vacantly around him and ask to be allowed to sleep. His voice was dull and monotonous. Though he lay curled up in bed there was no evidence of meningeal involvement. The C.-S.F. contained 20 lymphocytes per c.mm. and 70 mg. of protein per 100 c.cm. Neither chlorides nor sugar were diminished. The Lange curve was negative and the Wassermann reaction of his blood and C.-S.F. was negative. There were no abnormal findings in his urine.

His answer to a question was usually a drowsy nod or shake of his head. He had no memory of his journey to the hospital or of having been seen in the out-patient department that afternoon, and said that he had been in the ward for a week. He was a professional footballer, he said, who had been taken to hospital from the football field, where he had injured his knee playing for Margate. As a professional footballer he earned £2 a week. (He is in fact a shop-assistant.) He did not know what hospital he was in, and could not give the date or the day of the week. He believed the month to be October. At simple calculations he was slow and inaccurate.

thalamus. Clinical corroboration had been given by Penfield's case of "diencephalic epilepsy." Experiments on mammals suggested that the pars posterior of the pituitary had no particular function, though the evidence on polyuria was conflicting. The evidence for a hypothalamic-pituitary mechanism was very uncertain.

NERVOUS CONTROL OF THE CIRCULATION.

Prof. SAMSON WRIGHT said that workers in this country had never seemed able to accept the idea that the cervical sympathetic controlled the cerebral vessels, but the early evidence for this had been amply confirmed. Stimulation of the nerve caused marked constriction of pial arteries and a rise of blood pressure in them. The same story could be told of the pulmonary and coronary vessels, except that the vagus constricted and the sympathetic dilated the coronary arteries. The sympathetic was vasoconstrictor to the peripheral vessels, both in skin and in muscle, and sympathectomy would produce dilatation in cases of abnormal vasoconstriction; for instance, in Raynaud's disease. All the arterioles and veins of the body were under vasomotor control to an important degree. The sympathetic was vasoconstrictor to the veins, but vasodilator fibres were also found in the sympathetic fibres and in the posterior nerve-roots. Action currents had been observed in sympathetic fibres; they travelled rather slowly. Both sympathetic and para-sympathetic probably acted by liberating chemical substances peripherally—the former an adrenalin-like substance and the latter an acetyl-choline-like substance.

The carotid sinus—a dilatation at the bifurcation of the common carotid—and the aortic arch contained nerve ends the afferents from which influenced the vasomotor centre, the heart-rate centre, and the adrenalin-producing centre. The endings were extremely sensitive to slight pressure changes and might be called "buffer nerves": they exerted a tonic inhibitory influence on the bulbar circulatory centres and reflexly adjusted heart-rate, arterial tone, and adrenalin secretion to bodily needs. Section of these nerves might cause persistent arterial hypertension, and in rabbits, a marked breakdown of the media. A rise of blood pressure, through the aortic or carotid nerves, would decrease adrenalin secretion, and vice versa. Whenever the pressure tended to alter, these nerves tried to restore it, and they functioned so effectively that extensive damage could be done with practically no change of blood pressure.

THE SYMPATHETIC SYSTEM AND THE ALIMENTARY TRACT.

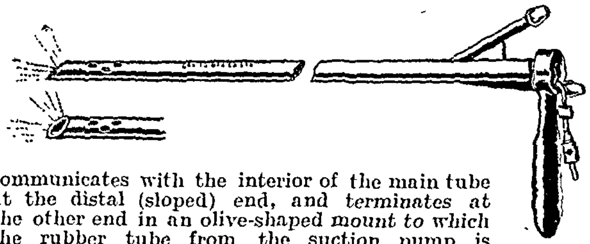
Dr. A. F. HURST described the ileo-gastric and gastro-colic reflexes, saying that in the last few feet of the ileum food collected, and appeared to be actively churned and digested, only passing into the cæcum just after more food entered the stomach. The mass movement of the colon likewise only occurred just after a meal. Many cases of constipation depended on disturbance of these normal sympathetic reflexes. The œsophagus was sensitive to thermal stimuli, but the rest of the canal was sensitive only to distension. All movements depended on increased tension. Very slight tension was the stimulus causing the reflexes; rather more tension caused a feeling of fullness: and more still produced pain. Distension of the pelvic colon produced a sensation of fullness in the lower abdomen, but distension of the rectum produced the call to defæcation. In tabes more than double the normal degree of tension might be required to produce the call, and also the effect was more prolonged. The only known organic disease of the sympathetic nervous system was seen in achalasia of the cardia; the cardiac sphincter failed to relax before the peristaltic waves on account of disease of Auerbach's plexus—either active inflammation with round-celled infiltration, or degeneration. Hirschsprung's disease was an achalasia of the anal sphincter and in a fatal case a similar degeneration of Auerbach's plexus had been found.

PAROXYSMAL SYMPATHETIC OVER-ACTIVITY AND THE OCULO-SYMPATHETIC.

Dr. RUSSELL BRAIN said that sham rage could be produced by a very small incision on the medial aspect of the frontal lobe without removal of any part of the cortex. A considerable variety of attacks comparable with sham rage might occur in man and might be primarily psychical—rage or fear—or primarily physiological—epileptiform. Dr. Brain described illustrative cases. The physiological type—diencephalic epilepsy—was characterised by widespread discharge from hypothalamic centres which had been cut off from higher control. In the psychic types the attack probably started at a higher level than in the physiological types. The nervous mechanism involved played a part in such states as mania, anxiety neurosis, and toxic goitre.

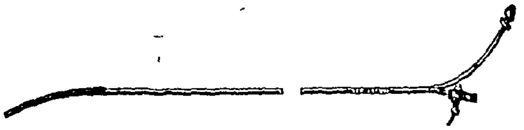
The oculo-sympathetic fibres had a cortical representation in animals, both in the frontal and occipital lobes, and a descending path ran thence to the thalamus and brain-stem and to the upper dorsal segments. The fact that a terrifying sight could cause pupil dilatation presupposed these connexions. True enophthalmos occurred as the result of ocular sympathetic paralysis, which might be caused by brain-stem, thalamic and lateral medullary lesions. Over-activity of this system caused retraction of the eyelids and was often associated with central lesions in the neighbourhood of the posterior commissure. Retraction of the upper lid might be the first symptom of exophthalmic goitre, but exophthalmos could not be produced experimentally by giving thyroid or thyroxin. Dr. Brain described illustrative cases of exophthalmos after encephalitis; and of exophthalmos associated with ophthalmoplegia. Whatever might be the ætiology of exophthalmic goitre, he concluded, exophthalmos, lid retraction, and other symptoms of sympathetic over-activity usually associated with thyroid excess might be produced by organic lesions of the brain, in the absence of thyroid enlargement.

Dr. LANGDON BROWN paid tribute to Gaskell's work on the sympathetic system and said that the most important recent work had been in relating the diencephalon to the autonomic system. He quoted Cushing's description of the small deep-hidden region of the pituitary as the centre of all primitive life, vegetative and emotional, lying between the cortex on the one hand, and the ductless glands on the other. The sympathetic system was arranged to work over large areas of the body at once. The general effects of its stimulation were to prepare the body for a struggle, whereas the general effects of the cranial para-sympathetic were to conserve energy and build up reserves, the sacral portion being expulsive. When one was stimulated the other was inhibited. The rhythm of life depended largely on the fluctuating balance between the two. The two reactions to danger: violent preparation for fight or flight, and complete immobility, permitted of no compromise. We had at present hardly any knowledge of the morbid anatomy of the system, but it certainly of the distal end has however been redesigned to allow forward illumination by means of a special lamp. The bronchoscope consists of a rigid metal tube, the distal end of which is sloped at an angle of 50° and slightly thickened round the edge to prevent trauma. A second much smaller tube is let half-way into the wall of the main tube and carries the lighting attachment. Alongside this small tube and outside the main runs a third channel which communicates with the interior of the main tube at the distal (sloped) end, and terminates at the other end in an olive-shaped mount to which the rubber tube from the suction pump is connected. The lamp is screwed on to a fitting carrying the electric wire connexion in the interior, and a suitable connexion for the cable at the other end. It is held in position in the channel by means of a pin engaging in a transverse hole in the handle of the instrument.

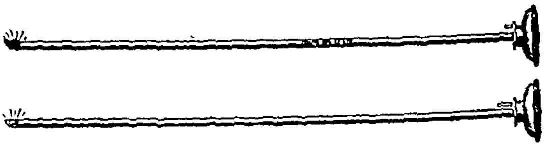


The lamp, specially designed for this instrument, produces both parallel and radial beams of light and the distal (sloped) end of the combined main tube and lamp channel is so arranged as to allow free exit to the light in all directions. A section of a bronchus approximately 3 in. long is therefore evenly illuminated and can be examined either with the naked eye or with the aid of telescopes. Of these three types are used. For ordinary diagnostic purposes the direct-vision telescope is the most useful, structures at 2 in. distance are slightly magnified (× 1·5), those nearer the lens correspondingly more. The second telescope, thinner in diameter and also 3 in. longer, is fitted with a deflecting prism and lamp. It is mainly used for the examination of the lateral bronchi and in conjunction with operating instruments. The third telescope, for retrograde vision, is solely for the inspection of the upper lobe bronchi. These telescopes are anchored to the bronchoscope by a simple pin fitting.

When pus, &c., is found in the main bronchi it is aspirated through the aspirating channel incorporated in the bronchoscope, as mentioned above. A separate suction tube with flexible tip is, however, necessary to aspirate the lateral bronchi and cavities. For some time we had difficulties in emptying constricted bronchi, since it is obviously impossible to aspirate a hermetically sealed cavity. To overcome this trouble we devised a suction tube incorporating a very fine malleable air tube running very near to the end of the flexible portion of the main tube. We found this addition also very useful, apart from its original purpose for washing out a cavity, since the lumen is large enough to allow of the passage of non-viscous fluids such as saline. The procedure is very simple; the stopcock on the main tube is shut, a few cubic centimetres of saline are injected through the fine tube, and immediately the cock is turned the whole is aspirated.



In the construction of these instruments we are much indebted to Mr. R. Schranz, of the Genito-Urinary Mfg. Co., Ltd. (the makers of the instruments), 28A, Devonshire-street, W.1, for the large amount of time he has spent with us in perfecting the instruments and for his mechanical ingenuity and advice without which we should have been much handicapped.



A. J. SCOTT PINCHIN, F.R.C.P.,
London, W. H. V. MORLOCK, M.R.C.P.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE.

COMBINED SECTIONS OF NEUROLOGY AND MEDICINE.

AT a joint meeting of these sections held on March 17th the chair was taken by Prof. A. STANLEY BARNES, President of the Section of Neurology. Prof. H. H. WOOLLARD opened a discussion on the

Visceral Functions of the Sympathetic Nervous System.

He said that most of our knowledge of the sympathetic nervous system was due to English workers. One of the most important recent advances had been the introduction of Langley's work into surgery; it had been shown that large parts of the sympathetic nervous system could be removed without apparent hurt. All workers had tried to bring the intrinsic systems of Auerbach and Meissner into relation with the extrinsic systems, but they appeared to be quite independent. The relationship of muscle tonus to the sympathetic system had broken down on anatomical grounds, as the non-medullated fibres concerned had been proved not to be sympathetic; sympathectomy did not abolish tone. Nor did the association of pain with the sympathetic system lie on any solid foundation. Every fasciculus going to a blood-vessel contained medullated as well as non-medullated fibres which might run for some distance with the vessel before rejoining the trunk. The sympathetic system appeared to exert some continuous tonic effects, while others could only be elicited by stimulation. In emergency-conditions it functioned as a whole. It had certain inconstant functions at times, such as the effect on the sweat glands and in the alimentary canal. In fact, the system remained much where it had been left by Langley. The parasympathetic might be looked on as restorative and anabolic, and the sympathetic as making more available the energy of the motor system.

The real interest had shifted from the periphery to the centre, though great difficulty was experienced in unravelling the autonomic centres in the diencephalon, partly because of its inaccessibility and partly on account of the many short neurons which made up the fibre tracts in this region. No function had been found for the pineal gland, but the basal part of the diencephalon contained a number of nuclei having the small-celled structure of sympathetic centres. The subthalamic nucleus was the interesting part in the hypothalamic complex; it seemed to have no relation with cerebrum or cerebellum. Its large cells depended for their integrity on the corpus striatum, but its small cells were regarded as an autonomic centre. The system included part of the thalamus and part of the striatum, and was believed to be associated with various metabolic functions. The importance of the hypothalamus as a sympathetic centre was supported by comparative anatomy, embryology and experimental work, particularly the condition of "sham rage," the anatomical centre of which lay in the posterior half of the hypothalamus and the most caudal and ventral part of the adjacent utilised seven full days after the final defervescence since the serum was richest in antibodies at that time. With a person incubating measles the injection should be made within six days of infection if complete immunisation was desired: during the seventh, eighth, and ninth days from the time of infection inoculation of convalescent serum would only produce attenuation of the attack. One difficulty lay in deciding the exact date of exposure to infection.

The donor should preferably be over 10 years, though Dr. Pierret mentioned that he had sometimes obtained blood in hospital from children as young as 3 years; he should be healthy, free from syphilis, tuberculosis, and malaria; defervescence should be complete; and precautions should be taken as far as possible to avoid taking serum from a patient in the incubation stage of another infectious disease. About 50 to 60 c.cm. could be taken from a child, and 80 to 100 c.cm. from an adult. The serum should be kept in a refrigerator for at least four days before use, to kill any treponemata, and should be subjected to bacteriological culture and the Wassermann test. Properly prepared and kept, the serum remained active for several months. Preference in its use should be given first to infants, next to children under 2 or 3 years of age; in practice, preference was also usually given to hospital cases and to delicate children, to children in families and schools, and to convalescent children. If a case of measles occurred in a hospital ward all the other children should be immunised, and the prevention of an epidemic in these circumstances was the greatest benefit of seroprophylaxis. Young children required a dose of 4 c.cm., children from 3 to 10 years 7 c.cm., and older children 9 to 10 c.cm. Whole blood was only half as active as serum. Failures with seroprophylaxis were few if the technique was adequate. General reactions, with rise of temperature, were occasionally met with, but no cases had been recorded of shock with rigor and collapse.

EXPERIENCE IN THIS COUNTRY.

Dr. **J. A. H. Brincker** said that Bordet's vaccine had been tried in whooping-cough in two L.C.C. hospitals during the past year, but the results obtained were not as favourable as those described by Dr. Pierret. In each hospital the vaccine had been tried in 100 cases, with suitable controls, but no difference had followed its use either in symptoms or incidence of complications. For some years Dr. Nabarro had been using convalescent serum for measles at Great Ormond-street with great success. Recently adult serum, obtained preferably from young men and women who had had measles earlier in life, had been used for the protection of contacts in hospitals, institutions, and residential schools, with valuable results. He was interested to learn that blood had been taken from children as young as 3 years of age. The feeling in this country had been that the young convalescent should not be deprived of blood, and hence the supply of convalescent serum was strictly limited. The injection of whole adult blood had been tried extensively in America, but the tendency in this country had been to concentrate on the use of convalescent and adult serum.

Sir **Almroth Wright** thought that Dr. Pierret assumed too readily that the blood was richest in antibodies directly after the disease. In typhoid the patient scraped through with no balance of antibodies to spare. In whooping-cough, where the organism was known, it should be possible to assess the value of vaccines accurately by scientific methods, not merely by clinical impressions. The vaccine used in this country had certainly been exposed to heat, and he would like to learn a more satisfactory method of preparation.

Dr. **W. Gunn** noted that in France clinicians appeared to get good results with smaller doses of convalescent serum in measles than were in use in this country. He thought that possibly this was related to the indefinite views held by practitioners on effective exposure to the disease; they were inclined to regard all children in the same classroom as contacts when a case of measles appeared, although some of them were not within striking distance of the infection. This point of view would mean, of course, that more children were given the chance of protection than were actually infected, and so would improve the statistics obtained. In seeking the optimum dose of serum for protection of children in his wards, and using controls, he had found a minimum dose of 5 c.cm. of serum to be necessary. In children over 3 years the dose could be decided by multiplying the age of the child by 2 and giving the resultant number of cubic centimetres. He regarded attenuated cases as failures, because the aim was to have no further cases in the ward. He did not consider that blood should be taken from a child of less than 5 years. The results of the use of adult serum in the London County Council hospitals had been fairly satisfactory; a minimum dose of 10 c.cm. was necessary, and, beyond that, double the dosage of convalescent serum had been used. The results had not been quite as good as with convalescent serum; if adult serum was given before the third day the attack was prevented in 99 per cent. of cases; if given after the third day attenuation of the attack was secured, and after the eighth day no effect was obtained. There was reason to hope that it would be possible to concentrate adult serum, so that smaller doses would be effective. After nine to twelve months in storage the serum was known to deteriorate, but it was possible that this difficulty would be overcome by drying.

THE DANGER OF INFECTION WITH TUBERCULOSIS.

Dr. **David Nabarro** said that his experience of the use of convalescent serum agreed with that of Dr. Pierret; the attack had been prevented in 98 per cent. of his cases, but it was not possible to say that all the children treated would have developed measles. He had recently experienced more failures, probably because he had been using serum nine to ten months old. An attenuated attack gave the patient lasting immunity, which was an advantage. Some physicians were opposed to the use of convalescent serum because they thought that in using serum obtained from children there was a danger of inoculating the patient with tuberculosis; tuberculosis was a common sequel to measles and whooping-cough in children. As Dr. Nabarro obtained his serum from adults and filtered it through a Zeiss filter he thought the danger of introducing infection was negligible. On several occasions, however, children had developed considerable reactions, with rise of temperature and malaise. He thought it most desirable to find a method of concentrating serum.

Dr. **J. D. Rolleston** said that the English experience of the value of a vaccine in whooping-cough was less favourable than the French. He thought that whooping-cough might sometimes be spread by the occurrence of unrecognised forms of the disease in adults, as in the case described by Dr. Pierret. Adult serum used in measles sometimes procured attacks so attenuated that it was difficult to say whether the patients had measles or not, and it expressed itself in emotional disturbances. Many psychoneuroses were based on subconscious fear, and a state of continued fear was capable of producing the symptoms of which psychoneurotics complained. *In many diseases of this kind the action of the* sympathetic system showed dissociation or perseveration. Through interaction with the ductless glands, the sugar metabolism might be affected. Evolved in a subconscious plane, the sympathetic remained for ever beyond the control of the will.

Prof. E. D. ADRIAN mentioned the relation of the sympathetic to respiration; the tonic discharge to blood-vessels ran rhythmically in phase with respiration. The sympathetic discharge was not smoothly continuous but very delicately poised. The vasomotor centres had no specific pressor nerves; all the nerves acting on them were inhibiting. They were always being stimulated by the respiratory centre.

SECTION OF EPIDEMIOLOGY.

AT a meeting of this section on March 16th, with Prof. MAJOR GREENWOOD, the President, in the chair, *a discussion* was held on

Biological Prophylaxis and Treatment in Measles and Whooping-cough.

Dr. ROBERT PIERRET, in his opening address, said that physicians and doctors in private practice in France saw more of infectious diseases and had a closer concern with their prevention and treatment than did their colleagues in England, where infectious diseases were linked up with the practice of public hygiene. In consequence there had developed in France a professional outlook upon infectious disease which was more often determined by the teaching of recognised masters than by the evidence of public health records.

In *whooping-cough* there were three aids to diagnosis—namely, the isolation and culture of the Bordet-Gengou cocco-bacillus, the intradermal test, and a combined intradermal and therapeutic test of the value of which he was satisfied. For successful culture the material must be sown directly on to a blood medium. A method more successful than that of making the patient cough into a Petri dish was based on the observation that, at the onset of a spasm, the patient gave two or three coughs with the mouth closed; infected material was therefore expelled in the nasopharynx, and a specimen could be taken from this region by means of a straight swab passed through the nostril in the infant, and by means of a curved swab introduced behind the soft palate in children over 3 years. The intradermal test for whooping-cough consisted of the injection of one drop of the vaccine of Nicolle and Blaizot, in which the organism, killed by fluoride, was present in the concentration of 250 million per 1 c.cm. In addition, Dr. Pierret said, he made a practice of injecting the remainder of the contents of the 1 c.cm. ampoule elsewhere, and had found that this often arrested or reduced the cough, especially if the injection were repeated on the two following days.

The biological agents at the disposal of the medical profession for the prevention of whooping-cough were (1) serum of convalescents, (2) Nicolle's vaccine. The serum of convalescents was little used in France; results were similar to those obtained with measles convalescent serum, the action of the serum being principally abortive but relatively rarely curative. The action was more definite if the serum was given early in the disease. Nicolle's vaccine had been the subject of considerable experiment, and was being used increasingly in France. One injection was insufficient, and it was wiser to give, on alternate days, three injections of 1 c.cm. of fluorised vaccine containing 250 million organisms per 1 c.cm., and *with this method he could claim 90* per cent. of successes in the protection of contacts. It was important that the vaccine should contain numerous strains, and the organisms, if not living, should not in any case be killed by heat, which reduced the therapeutic value of the vaccine. A wider use of vaccinotherapy would, in his view, stifle epidemics and render whooping-cough one of the least important instead of one of the most serious epidemic diseases. Children vaccinated before the development of symptoms or during the catarrhal stage did not acquire a lasting immunity, and might contract whooping-cough a year or two later.

The present position with regard to vaccinotherapy was as follows: (*a*) Negative or partial results were obtained if vaccines were used after the third week of the disease—i.e., after the whoop had been established for more than ten days, and when it was no longer possible to demonstrate the presence of the Bordet-Gengou bacillus. The fixation test had by this time become positive, and the patient had developed all the immunity of which he was capable. (*b*) Results were more satisfactory if vaccinotherapy was used in the second and third weeks of the disease before the whoop became established. Cough was reduced and vomiting might cease after the third or fourth day of the treatment, and occasionally there was complete repression of the disease after two to four days; treatment must be continued or recurrence of the whoop was likely. Children and infants treated by this method remained in good health, and Dr. Pierret had never seen any of the usual complications of whooping-cough in patients treated early. If insufficiently concentrated, wrongly prepared, or given too late, vaccines gave unsatisfactory results. Prophylactic doses recommended varied from one to three injections of 1 c.cm. of a suspension containing from 250 million to 5000 or 6000 million organisms per 1 c.cm., at intervals of two or three days. Dosage should be reduced to one-half or three-quarters for infants. Healthy adults in contact with the case should be vaccinated. In one case the doctor was found to be infecting his patients.

Measles was responsible for a larger total mortality than any other infectious disease. In communities of children and families the secondary cases were the most numerous, and the suppression of these would mean a great economy. Convalescent serum had no therapeutic value, probably because it was insufficiently rich in antibodies. It would be interesting to know whether convalescent serum was richer in antibodies than the serum of a person who, little by little, had been experimentally accustomed to resist the infection. Serum from nurses in a measles ward was more protective than serum obtained from ordinary persons who had had measles long before, and had not since been in close contact with cases. Convalescent serum was not necessarily free from the virus or its toxins, though their potency was *inferior to the antibodies present; it* was conceivable, therefore, that the injection of convalescent serum might involve a danger of infection. Valuable data might be obtained by injecting serum obtained at varying intervals after defervescence. Another objection to convalescent serum was the short duration of the immunity, protection lasting only three or four weeks. There was, moreover, *difficulty* in obtaining a sufficient supply of the serum and in finding voluntary donors. The donor should be with sepsis than the others, but even so the clot was usually formed at some distance from the area of sepsis. In all probability the thrombosis started within 24 hours, while the limbs were stretched, immobile, and flaccid. The valves appeared to form centres of attraction for the formation of clots and the clots often showed valve markings.

One of the most important measures for the prevention of thrombosis was to put the patient in a posture which would not compress and flatten out the femoral veins. Promotion of the circulation by massage was also valuable.

HUNTERIAN SOCIETY.

At a meeting of the Hunterian Society on March 21st, with Dr. DAVID ROSS, the President, in the chair, a discussion on the

Evolution of the Municipal Hospitals

was opened by Dr. W. BRANDER. In one sense, Dr. Brander said, the municipal hospitals had not evolved. They had been created, by a stroke of the pen on April 1st, 1930, when the hospitals previously under the control of the boards of guardians passed into the hands of the municipal authorities. The study of the development of these hospitals alongside the development of the voluntary hospitals afforded an interesting comparison. Since their student days most members of the medical profession had realised that the relation between poverty and disease was reciprocal; poverty begot disease and disease poverty. Medical, social, and economic factors must be considered in deciding the suitability of a patient for admission to hospital. There were three strata of society for which provision must be made: there were those wealthy enough to cater for illness in their own homes or in nursing homes; those who were economically sound until confronted with the additional expense of illness, and for whom the voluntary hospitals catered; and there were those who were never economically sound. Persons in the third group might be accepted at voluntary hospitals, but these hospitals had a discretionary right to pick and choose their cases. With the municipal hospitals the case was different; they were obliged to treat every case sent to them, and were allowed no discretion.

The voluntary hospitals in the early days had begun as voluntary and religious institutions for the shelter of the wayfarer and the sick. The work of the Sisters of Charity, the almshouses, refuges for the insane, and lazar houses had all led up to the foundation of the great voluntary hospitals. St. Bartholomew's Hospital and St. Thomas's were two of the oldest foundations and were originally the catch-alls for the most variegated population. Poverty was the common factor among those admitted to these early institutions, and though they undertook, where possible, the care and cure of the body, their primary concern was the care of the soul. In the fourteenth century the growth of the wool trade, the expansion of pasture land, and the Black Death were all responsible for initiating a considerable migration of the poorer classes from place to place, and it became a duty of the Church to care for them, while delinquency among them was the province of the magistrate; out of this arrangement rose the parish, which was an ecclesiastical, not a civil, unit. In 1601 the first Poor-law Act was passed, in the reign of Elizabeth. Industrial conditions were bad, and the Act remained much the same for the next 200 years. Under it, an overseer, the precursor of the guardian, compelled the collection of rates to maintain the old, the blind, and the helpless. The workhouses were foreshadowed in cottages for the idle who would not, and the impotent who could not work. In these there were intermingled the old and the young, the healthy and the sick, the sane and the insane; sanitary conditions were indescribable, and there was little care of the sick.

In the eighteenth century industrial conditions became still more acute, and landlords complained of the poor-rate. In 1843 a Commission was appointed which was superseded by the Poor-law Board and then by the Local Government Board, and finally by the Ministry of Health. In the early days of the workhouses there was no accommodation for the destitute sick except in the general wards of the workhouse; these had never been intended for the sick, and the public conscience demanded changes which were important in the evolution of the municipal hospitals. In 1868 the Metropolitan Act was passed which admitted of the provision of infirmaries separate from the workhouses. Destitute or sick persons had to be admitted through the relieving officer, and although destitution had never been defined by Act of Parliament, there began to be a relaxation in the accepted meaning of the term: guardians were told that they could judge individual applications on the evidence, and that a person might be regarded as destitute of some form of medical relief though he might not be destitute in other respects.

In a poor-law hospital in the north of England in the old days, Dr. Brander had seen the final stages of all types of chronic disease, every form of tertiary syphilis and of malignant disease too far advanced for treatment. The diseases were the same as those found in any ordinary acute hospital, but the patients were all candidates for the grave. But even before the 1929 Act the work of the poor-law hospitals had begun to encroach on that of the voluntary hospitals, though without intention or design on the part of the guardians. The primary cause was an urgent social need. At the time of the enforcement of the Act the London County Council took over 18,000 beds for acute cases, 10,000 for chronic sick cases, 15,000 beds from the Metropolitan Asylums Board, and 35,000 mental hospital beds. The standard of work in some of the hospitals transferred was equal to that found in the large voluntary hospitals.

MEDICAL EXPERIENCE IN THE MUNICIPAL HOSPITALS.

Dr. PHILIP HAMILL said that he had a great admiration for the work of the municipal hospitals. They were faced with all the cases that the voluntary hospitals rejected. It was at the municipal hospital that the later breakdowns in the course of chronic disease could be seen, and he always advised newly qualified men to take an appointment in a municipal hospital after finishing their house appointments in their own hospital. He considered that the builders of the municipal hospitals had shown great forethought when they placed the buildings in the outlying zones of London. He held no brief for rebuilding voluntary hospitals in the inner zone. There was an opportunity in the municipal service for improving the training of nurses: they could, for example, spend part of their general training at fever hospitals.

Dr. NATHAN RAW described the position in a large Liverpool infirmary 35 years ago. He had been superintendent, with four resident medical was even safe to leave them in a scarlet fever or whooping-cough ward.

Captain S. R. DOUGLAS said that there was no particular reason why measles should resemble typhoid in antibody formation. Following an attack of yellow fever the patient had a high degree of serum protection, and this usually lasted for life. It had been found, by experiments on distemper in dogs, that convalescent serum would give protection against a considerable amount of virus. If a large dose was given after the onset of symptoms, the temperature fell and the dog developed solid immunity; a concentrated dose given later had the same effect. The difficulty of obtaining concentrated measles serum lay in the limited supply of blood. The ideal would be to find an animal which took measles, when sufficient serum could be obtained to treat all cases.

Sir GEORGE BUCHANAN mentioned the occasional outbreaks of a type of diphtheria which was not counteracted by full doses of antitoxin. Though the notifications of diphtheria were rising the death-rate was fairly constant, and had not so far been influenced by these cases of diphtheria gravis. Dr. Pierret had suggested that Bordet's vaccine should be given in whooping-cough before the development of the whoop; how was the diagnosis to be made at this early stage?

Dr. E. W. GOODALL added that in some cases the first symptom was the whoop; how could an earlier stage then be diagnosed? He had performed autopsies on 22 children who died following whooping-cough, and in seven of these death had been due to acute miliary or acute pulmonary tuberculosis. Among autopsies on 130 measles cases tuberculosis was found in seven. He thought, therefore, that whooping-cough was more likely to be followed by tuberculosis than measles.

HARVEIAN SOCIETY.

AT a meeting of this society held at Paddington Town Hall on March 17th, the chair being taken by Mr. C. P. G. WAKELEY, the President, Sir BERNARD SPILSBURY delivered the Harveian Oration on

Pulmonary Embolism.

In some of the cases he had seen, he said, the clots had been so long that they projected beyond the pulmonary artery, into the right ventricle, death being due quite as much to interference with the function of the valve as to blockage of the artery. He proposed to draw material for his observations from 120 cases of pulmonary embolism on which he had performed autopsies, and he would show that this condition was responsible for a fair number of sudden deaths in apparently healthy persons. The main factor in the production of the thrombi causing pulmonary embolism was alteration in the flow of blood in the veins. This might arise as a result of enfeeblement in the general circulation, of diminished suction action of the chest, decrease or absence of muscular contractions in the limbs, local interference—pressure on veins—or disease of the vessel walls and varicosity. In a very large proportion of his cases sepsis had not been a factor, and even when sepsis had been present the thrombosis had been at some distance from it. He had never yet examined a pulmonary embolism which he could describe as a septic embolus. A factor in venous thrombosis which was most difficult to assess was altered coagulability of the blood; some cases of thrombosis and embolism were undoubtedly partly due to this. Coagulability was raised by hæmorrhage, crushing of tissues, and some forms of sepsis. In only one case of his series, however, could altered coagulability be regarded as the sole cause.

In a very large proportion of cases the embolus arose from a thrombus in the femoral or iliac veins; in about 90 per cent. the thrombus was in the lower limb or pelvis. Emboli did not conform to the shape of the vessel in which they lay and were generally small; the size of the little finger or of a pencil. Their length varied from 2 in. to 9 in.; their diameter varied in different parts, and they had irregular branches which did not conform with those of the vessel in which they lay. They were heaped up in that vessel, often packed so tightly that they were only dislodged with difficulty, but they were not adherent unless there had been more than one attack before death; they were sometimes solid and sometimes cylindrical or ribbon-like. The older they were, the firmer, but they were always firmer than any post-mortem clot. Usually the surface was light-coloured with a very fine mottling. Besides the fatal embolus, others might be found in the heart or in one of the main veins, and infarcts might be seen in the lungs.

Death might be due to sudden strain on the right heart or to the rapid fall of blood pressure in the lesser circulation. Even when death had occurred under anæsthesia, while the patient was being closely watched, there seemed to be variations in the symptoms; these probably depended on the size of the embolus. In some cases the right heart was paralysed and in others, with a rather smaller embolus, the diminished flow of blood through the lungs brought about respiratory distress.

ELEVEN GROUPS OF CASES.

The 120 cases in his series could be grouped according to the conditions in which embolism might occur: (1) ambulatory—chiefly old people with flabby dilated hearts and poor circulation; often the thrombosis started in varicose veins and spread up the thigh. (2) After very slight accidents in feeble old persons. (3) In serious cardiac lesions in young people. (4) In complete paralysis; one man had died of pulmonary embolism only three days after a grave injury which had rendered him paraplegic probably because of the absence of muscular movements to promote circulation. Immobilisation of a part might have the same effect. (5) After pressure on the veins—e.g., from a hæmorrhage, abscess, or tumour. (6) In cirrhosis of the liver slowing the hepatic circulation. (7) In cases of varicose veins (8) After the injection treatment of varicose veins there were only three examples of this in his series so the complication was rare. In two cases sodium salicylate and in one sodium morrhuate had been used. No evidence of local sepsis could be found (9) In puerperal conditions—death usually occurring from the seventh to the twelfth day after labour without any signs of sepsis. In one or two of the ten cases involution had seemed to be retarded. Sir Bernard had only one record of pulmonary embolism from over 300 cases of abortion, many of them septic. Pulmonary embolism had occurred during healthy pregnancy—usually about the seventh month, presumably as a result of pressure on the pelvic veins. (10) Under anæsthesia. In many of these cases the embolism appeared to bear no relation to the operative procedure, but in others manipulation had undoubtedly dislodged a thrombus. (11) After operation; this group was more closely associated

REVIEWS AND NOTICES OF BOOKS

Diagnosis of Joint Disease.

By NATHANIEL ALLISON, M.D., F.A.C.S., Professor of Orthopædic Surgery, University of Chicago; and RALPH K. GHORMLEY, M.D., F.A.C.S., Assistant Professor of Orthopædic Surgery, Mayo Foundation. London: Humphrey Milford, Oxford University Press. 1932. Pp. 207. With 50 illustrations and 9 plates (6 in colour). 52s. 6*d*.

THE authors were inspired to write this book from the conviction that the diagnosis and classification of joint diseases, as it stands to-day, is inaccurate. Such observations as those made by Ghormley, that out of 41 positive diagnoses, only 66 per cent. proved to be correct, and, conversely, that out of 42 cases dismissed as non-tuberculous, 55 per cent. eventually turned out to be tuberculous, shows that all is not well with our present methods. Apart from certain histological findings in rheumatoid arthritis, upon which they lay greater emphasis than other workers, the authors do not claim to have made any discoveries; but they insist that only by investigating every case scientifically and evolving some comprehensive yet simple mode of classification can any progress be made in this most difficult subject. To this end they have collected 289 cases of joint disease during the last six years and have attempted in each case to find the answer to the questions: What is the ætiological factor? Which tissue of the joint is primarily affected? What is the nature of the change in the joint tissues? After marshalling all the facts, they come to the conclusion that in cases where the causative agent is known the type of arthritis should be registered under that head, but in cases where the cause could not be discerned, the best term for classification is that which accurately describes the characteristic primary changes within the joint. These changes could usually be grouped under two headings, proliferative and degenerative. They think that no useful purpose can be served by multiplying names to describe the same pathological process. Such conditions as we in this country variously call rheumatoid arthritis or atrophic arthritis, they prefer to place under the heading of proliferative arthritis of unknown origin, because, according to them, the primary change is a proliferative one, affecting the synovial membrane and the bone subjacent to the articular cartilage, and the atrophy, though a characteristic feature in the X ray plates, is really only a secondary change due to disuse. Similarly, what we call arthritis deformans, osteo-arthritis, or hypertrophic arthritis, they term degenerative arthritis of unknown origin, because they hold the primary change to be a degeneration of the matrix of the articular cartilage and such hypertrophic activities as exist to be secondary to the changes in the cartilage. Again, in discussing pyogenic infections, they would like to discard such variations as serous, seropurulent, and purulent, because these merely represent phases in the normal evolution of a suppurative arthritis, whatever the responsible organsim may be.

After a preliminary survey of physiological considerations, the authors proceed to discuss each group separately and at the end of each section append numerous case-histories with excellent X ray pictures and microphotographs. They quote the authority for every statement made, with the result that an extremely useful bibliography is provided and a wealth of information is compressed into a short space. No pains have been spared in the preparation of this work, and it leaves the impression of care, usefulness, and sincerity. Students, qualified or unqualified, wishing to interest themselves in this subject would find it an invaluable starting point to their researches.

Atlas du Cancer.

Neuvième et dixième fascicules. Les tumeurs des centres nerveux et des nerfs périphériques. By GUSTAVE ROUSSY and CHARLES OBERLING. Paris: Libraire Félix Alcan. 1931. Fr.80.

AN atlas in pathology may perform two useful services. The first is to provide a convenient work of reference for those engaged in diagnosis. The atlas compiled by P. Bailey and published in the Archives of Pathology and Laboratory Medicine (1927) is an example of a useful paper for this purpose. The other function of an atlas is the enlightenment of research workers in the same field, who may be greatly assisted by frank statement of convictions and difficulties. The specialist who lays his cards on the table in this manner confers a favour on his fellow workers, and this is particularly true when the ground covered is difficult and controversial, such as the classification of the gliomas. In this atlas text and illustrations are well balanced. The text is succinct and adequately descriptive; it embodies a good deal of speculation on controversial topics. The illustrations, which are mostly reproductions of water-colours, are admirably clear and instructive. The classification adopted is evidently based on that of Bailey and Harvey Cushing, but the object here is the representation of common types rather than an examination of their histogenesis or the inter-relationships between the different types. The types are correlated with those of other authors by lists of synonyms.

Much controversial matter is presented. In the drawings of the normal neuroglial elements that serve as an introductory plate, there is little appreciation of the finer structure of the oligodendroglial cell, and the student would find it difficult to distinguish it, in practice, from a small astrocyte. It is peculiar, too, that the method quoted for the demonstration of these oligodendroglial cells is a modification of a method that is selective for astrocytes—namely, Cajal's gold chloride sublimate method, rather than Hortega's specific silver carbonate method for oligodendroglia. This may possibly explain why the authors have encountered the unusually large proportion of 16 oligodendrogliomas in 251 cerebral tumours. Moreover their "oligodendrocytome à cellules fusiformes" is admittedly the type called by Bailey "spongioblastoma uni et bipolare." The cells of this tumour do not stain in the same manner as oligodendroglia, and hence the tumour would not be acceptable to most workers as an oligodendroglioma of any kind. Undoubtedly in this grouping the authors have been swayed by the theory that underlies their designation of the nerve-root tumours as peripheral gliomas. This theory is based upon two assumptions: the first is that the neuromas are tumours of the sheath of Schwann cell, the second that the sheath of Schwann cell is of ectodermal origin and therefore perhaps homologous with the oligodendroglial cell. Neither of these hypotheses is officers. Autonomy was demanded by the Local Government Board, and he and his staff had to perform every operation required. After 17 years he had performed 8000 major operations. Eventually extra assistance was grudgingly granted, and now the hospital had a full consultant and laboratory staff. In his opinion, the National Health Insurance Act should have its own hospitals, and he thought that in future the municipal hospitals would probably be transferred to the service of this Act. The system worked well in Germany.

Dr. W. H. F. OXLEY gave the point of view of a general practitioner in the east end of London. Until April, 1930, at the local hospital three medical officers had been in charge of 300 beds, and had been so severely overworked that he had avoided sending patients into the hospital. During the past two years, however, he had had the chance to realise the opportunities of a properly staffed municipal hospital, and he thought it possible that in the future these would be the leading hospitals of the country, centres of medical education with a personnel of professorial rank like the Scandinavian State hospitals. He thought that some liaison should be made between the voluntary and municipal hospitals to improve the obstetric teaching of medical students. The obstetric material at the disposal of the voluntary hospitals was quite inadequate. He suggested that it should also be possible to secure an interest for the general practitioner in hospital work, perhaps by offering him an appointment as clinical assistant.

THE WORK OF MEDICAL SUPERINTENDENTS.

Dr. J. B. COOK mentioned some of the reforms achieved by the medical superintendents of municipal hospitals. In 1899 night nurses used to be appointed permanently in these hospitals, but thanks to the efforts of the Society of Medical Superintendents this had been remedied, and the system of alternation now in action had been accepted. It was also thanks to the work of the Society in 1898 that cases of pulmonary tuberculosis were segregated, and not placed in the acute wards. He thought some general system of insurance should be instituted so that patients could pay something to the hospital during their stay in the wards. He agreed that it should be possible to augment the obstetric experience of medical students in the municipal hospitals, and though this might be at the expense of the midwife, it was preferable that the doctor, rather than the midwife, should see difficult cases. General practitioners unfortunately found it extremely difficult to keep appointments to time, and it was essential that hospital routine should follow a time-table.

Sir BRUCE BRUCE-PORTER thought that in future the work of the general practitioner would be purely preventive, and that all patients ill enough to go to bed would be sent into hospital.

Dr. W. E. A. WORLEY found that some patients who could afford the fees of a maternity home were going into the Hackney Hospital because they knew they would get excellent attention there at much lower rates. He thought that it would help the general practitioner if he were always informed of the treatment given to his patients while in a municipal hospital; at present this was not always done.

Dr. BAILEY said that he believed that separate infirmaries were created by an order of the Local Government Board under the Poor-law Act of 1832, and not as a result of the Metropolitan Act. He quoted the definition of destitution given to the Royal Commission in 1908 by their legal adviser, from which it appeared that anyone might claim to be destitute.

Dr. J. F. HALLS DALLY asked what the future policy of the L.C.C. was likely to be. He thought that the municipal maternity hospitals might be used for post-graduate teaching as well as for the training of students. He would like to see more beds set aside for the treatment of rheumatic children.

Sir THOMAS CAREY EVANS thought the voluntary hospitals suffered through being governed by lay bodies. Their funds were in consequence not economically spent.

Dr. D. A. COLES asked what would be done in the municipal hospitals to arrange for consultations with general practitioners about the cases they sent up.

Mr. HOPE CARLTON saw no reason why a doctor should cease to practise privately because he had entered the service of a municipal hospital; in the legal profession a man was able to practise even when appointed to some official post, such as that of recorder.

A vote of thanks to the speaker was proposed by Mr. MORTIMER WOOLF and seconded by Dr. JAMES I. P. WILSON, and Dr. BRANDER replied.

NON-INFECTIVE NEPHRITIS.—Referring to our report (p. 620) of his opening remarks on this subject at the Medical Society of London, Dr. A. Arnold Osman writes: "I did not say that in examining 2000 histological sections of kidneys from consecutive post mortems that 95 per cent. had chronic nephritis of a primary type, or even of any kind. I merely mentioned that, though not an histologist, I had, as a result of this examination, reached the conclusion that the figures of Herringham and others which I quoted on the incidence of chronic nephritis in cerebral hæmorrhage, heart disease, &c., and which I believed were based chiefly on the macroscopic appearances of the kidney, were substantially correct."

CHILDREN'S HOSPITALS.—Last year 2896 children were admitted to the general wards of Birmingham Children's Hospital and to the day ward 4042; new medical out-patients, 5728; new surgical out-patients, 9416. The average length of stay was 25 days, an increase of a fraction over a day. Research work carried out in the biochemical department during the year, the report says, has been concerned largely with the anæmias of infancy and childhood and with the possible connexion between nutritional anæmia of early childhood and prenatal feeding.—The Legislative Council and the House of Keys of the Isle of Man have passed the Education (Extension of Medical Treatment) Bill. The measure extends the provisions of the Education Act as to medical and dental inspection and treatment to children under school age, and enables the Education Authority to provide orthopædic treatment for young persons up to 21 years of age. It is estimated that the continuance of an annual grant of £500 for two years will enable all the urgent and the majority of the less urgent cases in the island to be dealt with.—The annual report of the Royal Hospital for Sick Children, Glasgow, urges the provision of a completely equipped orthopædic department which would form the centre of an organisation for Glasgow and mid and West Scotland. It is also desired to establish a research endowment fund whereby the entire resources of the hospital could be utilised for consistent and sustained inquiry into the diseases of infancy and early childhood. Last year the hospital treated in the wards 5856 patients, and there were over 22,000 attendances of out-patients.—The Dowager Duchess of Beaufort has opened the new wards in the reconstructed portion of the Bristol Royal Hospital for Sick Children. Although various wards were closed last year during building operations, over 1000 children were treated in the wards and there were nearly 5000 out-patients, over 1000 of them being women.

The Treatment of
Rheumatism, Lumbago,
Sciatica, Neuritis, Gout, etc.
where due to excess of Uric Acid,
by

AGOTAN (Howards)

Weintraud found that in gouty patients on a purine-free diet it **more than doubled the quantity of uric acid excreted in the urine.** Chase and Fine maintain that in normal and gouty individuals it induces an augmented excretion of uric acid in the urine and a decreased concentration in the blood by endowing the renal cells with **an increased power for eliminating uric acid**

Some Medical Opinions:

M.D. (London):

" I prefer to regard sciatica as a neuritis and not merely a neuralgia, and I further believe that the commonest cause of neuritis is uric acid. At all events **my most rapid and lasting results in its treatment have been obtained by that excellent preparation Agotan.** I have had marked success with it."

Capt. (R.A.M.C.):

" In our wet and cold camp of 1926 men were continually reporting sick with sciatica or lumbago. Conditions rendered most of the accessory means of treatment most difficult, **but Agotan—10 grs. thrice daily—cleared the trouble up in 3 or 4 days' time** despite the adverse conditions. In several cases taken at their very inception, so to speak, three doses proved sufficient."

M.D., C.M., D.P.H., etc.

" I have run through the whole gamut of B.P. remedies, and I have tried, I think, all the proprietary uric acid solvents of the present day, but after many years of experience **I have come to rely on Agotan as the most trustworthy preparation at present available.** The conditions in which it may be prescribed with confidence embrace all forms of subacute rheumatism, muscular rheumatism or myalgia, including sciatica, brachial neuritis, and gout, whether acute or chronic, and most of the gouty skin diseases. The last group often yields remarkably well to Agotan."

AGOTAN is the All-British make of Phenyl Cinchoninic Acid B.P.C. and is sold as powder in 1-oz. bottles, in 7½ grain tablets in bottles of 25 and 50, and in ointment form in collapsible tubes.

FREE SAMPLE sent to any Medical Man on request to the Manufacturers:

HOWARDS & SONS LTD. (Est. 1797), ILFORD, LONDON

well supported by observation, although the second enjoys a good deal of popularity in some quarters at the present time. Most pathologists, for the present at any rate, will prefer the theory that the neuromas are fibroblastic tumours, since this is in accordance with the evidence of differential staining.

Another distinctive point of view is found in the authors' designation of the cerebellar medulloblastoma as "neurospongiome." This nomenclature is based upon original work, as a result of which the authors claim that a large proportion of the cells in these tumours possess the staining reactions of neuroblastic cells. They resemble the small granular cells of the cerebellar cortex. This work is of considerable importance and, if confirmed, will greatly advance our knowledge of these tumours.

The interest of this atlas to the specialist is obvious. Those who are more concerned with the recognition of types of glioma in the course of routine work will also find it valuable; the authors show that much may be achieved in such recognition by the use of routine staining methods. They do not, however, belittle the importance of using a variety of different methods if a satisfactory analysis of the cytology of these tumours is to be obtained.

An Introduction to Tropical Pathology.

By T. BHASKARA MENON, M.D., M.R.C.P., Acting Professor of Pathology, Medical College Vizagapatam. With a Foreword by Major-General C. A. SPRAWSON, C.I.E., V.H.S., M.D., F.R.C.P., LL.D., I.M.S. Calcutta: Thacker's Press and Directories, Ltd. 1931. Pp. 210. Rs.10.

THIS small book, according to the preface, is intended mostly for undergraduate students in the tropics. It has but few pages, the type is large, and since many illustrations are included there is not much solid substance in the fare provided for the reader.

The author's opinions with regard to the infective stages of *E. histolytica* mentioned on p. 65 will not meet with general acceptance and the description of the pathology of blackwater fever might be considerably expanded. To bring the chapter on sprue up to date much more would have to be said about the types of anæmia and bone-marrow changes than the author has found room for. There is indeed little pathology in this book which is not dealt with at least as fully in the standard text-books on tropical medicine, and the absence of a fuller description of symptomatology in relation to pathology tends to make even this short book difficult to read. The illustrations are clear and the microphotographs are well reproduced.

Text-book of Gynæcology.

By SIDNEY FORSDIKE, M.D., F.R.C.S. London: William Heinemann, Ltd. 1932. Pp. 290. 15s.

THIS small book is intended for the use of students and practitioners. It is clearly and concisely written, the print is good, and the illustrations are exceptionally well produced for a text-book of this size. The views expressed are thoroughly conservative and will be generally accepted; the general arrangement of the material calls for no comment. On the other hand it is doubtful if students will obtain all the information they require for their final examinations from a book of this scope. Moreover, the compact style makes the assimilation of the subject matter a laborious process and demands much concentration. The popular standard works for the student of to-day are either comprehensive text-books or synopses, and there is much to be said for this grouping. This book is neither one nor the other. Mr. Forsdike's contribution might be of service to students who are starting their gynæcological appointments, for it will enable them to get a general survey of the subject with reasonable ease; he might with advantage develop a more ambitious volume on the same plan, for the subject is admirably presented and the general style is far above that of most books of this size. A few minor criticisms might be made. It is not customary to classify follicular and lutein cysts of the ovary under the heading of benign cystomata, and the material in the chapter on embryonic tumours requires rearrangement. The chapters on radium treatment, post-operative treatment, and gynæcological therapeutics are particularly good.

Practical Morbid Histology.

A Handbook for the Use of Students and Practitioners. Second edition. By ROBERT DONALDSON, M.A., M.D., Ch.B. Edin., F.R.C.S.E., D.P.H., Sir William Dunn Professor of Pathology in the University of London; Hon. Pathologist, Guy's Hospital. London: William Heinemann, Ltd. 1931. Pp. 487. 42s.

THE author has greatly improved this work by introducing illustrations into the second edition; the first was not illustrated and was therefore not likely to appeal strongly to students. This new edition, with over 200 beautifully reproduced drawings, should prove much more attractive in spite of its increased price. In the subject matter a number of additions and alterations have been made. The author's original intention was to confine the work to descriptions of histological appearances, thus providing a guide to the study of morbid histological sections; but the scope of the work has now been extended. Concise accounts of the pathology and of the morbid anatomy of the lesions are included as well as descriptions of their histology. A short section on parasitology and also a 40-page section on histological technique and stains have been added. The work is now a fairly comprehensive text-book of practical and special pathology; the subject is treated in a sound and orthodox manner, the writing is clear, and the essential points are well represented. The illustrations, all but two of which were drawn by the late Mr. Richard Muir, of Edinburgh, are mostly excellent; they possess that degree of the diagrammatic which gives the most effective interpretation of histological structure to the beginner. An unfortunate feature of the book is that these illustrations are not used to the best advantage. The author's opinion that illustrations are not really necessary in a book of this kind is recorded in the preface, and he has allowed this view to interfere with the proper development of the work; for, although he has inserted the illustrations, he has made no attempt to correlate his text with them. No reference is made to them, nor are they directly used to illustrate particular points discussed in the text. On pages 12 and 13 for example, the note on the plasma cell which describes its structure and appearance in some detail, gives no reference to the picture of a plasma cell on page 2. As a result of this incoördination many opportunities of simplifying the teaching of the subject are missed, and the whole book shows a lack of cohesion between component parts. Apart from this the teaching is sound.

THE LANCET.

LONDON: SATURDAY, MARCH 26, 1932.

THE PROBLEM OF CONVALESCENCE.

ILLNESS which neither terminates in death, nor drags on indefinitely without prospect of recovery, must pass through a stage of convalescence. It is during this stage, as ELIA inimitably showed, that the mutual bond between doctor and patient is apt to weaken, and as a consequence, the cure is often imperfect or needlessly delayed. The doctor, on his part, has labelled the case with a diagnosis, has finished all the urgent and most interesting part of the treatment, and knows that the patient is out of danger and should get better. Other acute cases, with their pressing calls on his time and thought, drive its memory from his mind, or he may feel diffident in urging further attendance and consequent expense to the patient, or on the other hand feel it unjustifiable to retain him in the occupation of a hospital bed. The patient, on his part, is reluctant to trouble, or to pay, the doctor more than is absolutely necessary and feels he must get back to work. This attitude may result in too early a return, an imperfect cure and possible relapse, or a long period of indifferent health. Among insured patients the opposite may happen. A middle-aged labourer, with wife and family, brings down a hernia at his work. He is put on the waiting-list of the local hospital and spends some weeks in idleness and anxiety about the operation he has been told he requires. In due course he is admitted, all goes well and he is discharged in three weeks with the injunction to take things easy for a time. He spends more weeks in idleness, reporting to his panel doctor for certificates at intervals, and inspecting his well-healed scar with profound distrust. Before long he is badly out of training, and has lost confidence in himself and broken his once well-established habit of regular occupation. When, and how, shall he return to work? To advise light work is useless: it is not to be had: with the labour exchanges crowded with able-bodied men, who will give him employment? So, with his family dependent on him, he clings to the slender income of sick benefit, rather than launch out into the stormy waters of the labour market, and another case under the Workmen's Compensation Act is added to the list at the county court. The man is neither a malingerer, nor the victim of traumatic neurasthenia, though he may be described as such by the opposing lawyers. he is suffering from the lack of a properly regulated convalescence.

In most districts the present hospital accommodation is adequate for the treatment of acute cases, but many patients are retained for a time, in the general wards, after they have ceased to require active hospital treatment, because they clearly are not fit to return home. And there is no alternative. The rate of turnover of the hospital beds is retarded and a long waiting-list accumulates. The usual solution suggested for this problem is the building of fresh hospitals and the enlargement of the old ones. But such a procedure is uneconomical while it does nothing to reduce the numbers of half-cured and semi-chronic invalids. The right solution would be to set up in connexion with every large centre an establishment specially designed, staffed, and equipped for the treatment of convalescent cases. In this country there are very few such establishments, although, for instance, the Astley Ainslie Institution attached to Edinburgh Royal Infirmary is a happy exception and an inspiring example. Many of the larger hospitals have annexes, on the outskirts of the towns they serve, which to a point supply the deficiency; but they can take only a small proportion of hospital patients and, unless large, they cannot work with economy or efficiency. What then are the requirements which an ideal institution should possess? First, no acute cases must be admitted, nor any case suffering from an incurable condition. The centre is not equipped to deal with the former and the latter will tend to dispel the atmosphere of optimism and steady progress to full recovery which is one of a good home's most powerful therapeutic assets. Secondly, it should be subdivided into sections to deal separately with various special conditions—cardiac, post-operative, orthopædic, nervous, and so forth; for each will want, to some extent, specialised treatment. Thirdly, it should be large enough to ensure that no case need be discharged before it has obtained the maximum of benefit obtainable. Lastly, it must possess ample facilities for providing, and enforcing, graduated recreation and work, both mental and physical. The last factor is, perhaps, the most important and difficult of all. It entails the organisation of games and physical exercise, garden work, farm work, and a variety of indoor trades and occupations, and the permeation of a tradition of discipline and morale so that all the inmates carry out conscientiously the tasks set them. Such an ideal is by no means unattainable. It is seen in a number of the best sanatoriums for tuberculosis, and on an even larger scale in such colonies as Enham and Papworth.

Finance is the rock on which such schemes founder and the present time of depression does not seem an auspicious one for the launching of such ideas. But there are certain aspects on the financial side which merit consideration. It should not be difficult to find buildings and estates which, with comparatively little adaptation could be made ideal. Throughout the country there are large houses, with grounds and farms attached, for sale at grotesquely low prices. The cost of maintenance will naturally be very much less than that in a general hospital, for fewer and less highly trained nurses will be needed, and the overhead charges and cost of equipment will be low. If properly organised, the institution should be able to keep itself in garden and dairy produce, do its own laundry and cleaning by the work of the patients, with the minimum of paid supervisory officials. Some

Reminders and Suggestions

For the
Treatment of
INFLUENZA, PNEUMONIA,
COUGHS, COLDS, BRONCHITIS, etc.

KINECTINE

An organic arsenical salt of Quinine indicated in Influenza, Acute Coryza, etc.

Tubes of 10 Tablets: Dose—One three times a day.

CRYOGENINE

(Lumière)

A particularly safe and reliable analgesic and antipyretic in all febrile conditions. Bronchitis, Pneumonia, Influenza, Pleurisy

Powder and Tablets: Dose—From 0·50 to 2·50 gm. daily as required.

ORARGOL

An electrically prepared Gold-Silver Colloid for general antisepsis and effective colloidotherapy.

Ampoules of 5 c.c. and 10 c.c.

By intravenous or intramuscular injection Orargol is capable of aborting serious cases of Influenza and Pneumonia, and exerts an antitoxin-like effect in acute infectious conditions.

Also supplied in special O.R.L. Outfit for Nasal Irrigation in the treatment of Rhinitis, Tonsillitis and Naso-pharyngeal inflammations.

Extremely valuable as a prophylactic against Colds and Influenza.

SYRUP CREOSAL

(Dubois)

A combination of Guaiacol, Calcium and Phosphoric Acid pleasantly flavoured with Syrup of Orange Flower & Cherry Laurel.

An excellent specific for Coughs—whatever their origin—Bronchitis, Laryngitis, and all Catarrhal Conditions.

SYRUP PERTUSSIS

(Gabail)

A combination of deodorised Valerianate, expectorants and sedatives presented in a palatable form with Syr. of Raspberry.

An effective medicament for the Paroxysms of Whooping Cough.

LITERATURE AND SAMPLES ON REQUEST FROM

The Anglo-French Drug Co., Ltd.,
238a, Gray's Inn Road, LONDON, W.C.1.

corpuscles which are available. It may well be, as he suggests, that this substance has a general influence on the metabolism of iron which is a necessary constituent of every cell in the body, and it is a striking and significant clinical fact that the first effect of giving liver to an untreated case of pernicious anæmia may be a great improvement in his sense of well-being two or three days before there is any perceptible change in his blood: he sits up in bed and asks for the newspaper and a cigarette without any alteration in his percentage of hæmoglobin or his reticulocytes, and it is difficult to believe that his general symptoms are due solely to anoxæmia. The connecting link between these two extremes is found in the anæmia with a low colour-index which occurs almost exclusively in married women, is much aggravated by pregnancy, and can be cured with massive doses of iron but not with liver. It has no satisfactory name; "microcytic anæmia" and "simple achlorhydric anæmia" both have the general disadvantages of all definitive names, and other anæmias have small cells, while about a fifth of the examples of this disease have not got achlorhydria. Considering that Dr. WITTS has been chiefly responsible for the recognition and study of the condition in this country, "Witts's anæmia" would be a convenient label until we know enough to fit the condition into some completely rational scheme. He has made too the fine discovery that the gastric juice contains the ferment which will generate from beef the substance which is missing in pernicious anæmia, though it has as little acid or pepsin as in Addisonian anæmia. Hence the megaloblasts can mature to normoblasts and the patient can be cured with ample supplies of the iron which is needed for the transformation of normoblasts to red cells.

These very substantial advances in knowledge have been due in the main to the intelligent use of two technical procedures—fractional test-meals and the precise measurement of the sizes of red cells inaugurated by Dr. PRICE-JONES. In minor degrees the exact enumeration of reticulocytes is a distinct improvement over the rather vague determination of polychromasia, and Dr. PIJPER's diffraction method has been very useful in giving an easy, if rather rough, method for ascertaining cell sizes. The study of red cell diameters has given us criteria for the identification of the different anæmias much more definite than we had before; the stomach-tube is mostly responsible for our new knowledge of the causation of those which depend on misfunctioning of the bone-marrow. Normal gastric juice contains acid, pepsin, rennin, and the hæmatinic ferment, and the products of its action are absorbed from the intestine. It may fail in various ways, most commonly in middle life. If it fails completely, we have megaloblastic Addisonian anæmia, and we get the same result if, as sometimes happens, the hæmatinic ferment fails while acid and pepsin continue or if bad intestinal absorption frustrates adequate gastric digestion. If it fails in everything but the hæmatinic ferment, we are likely to get Witts' anæmia owing to defective absorption of iron. The interplay of these considerations makes it easier to understand why a case of simple microcytic anæmia may develop into megalocytic pernicious anæmia and, occasionally, vice versa, and why some people with achlorhydria are quite well.

Finally, we would draw particular attention to the group of hæmolytic anæmias described in the third lecture. We have here pretty plainly an uncommon disease which needs much further study—so uncommon that combined effort is needed for its elucidation. Some examples have the characters of a subacute infection, and if the patient survives there is no prospect of a recurrence: the marrow is active and responds as it normally does to loss of blood. Rare and obscure diseases are apt to be put on one side until someone has provided some sort of background on which they may be looked at: we hope that Dr. WITTS has done this and roused an interest in a condition about which we want to know more.

THE STORY OF THE TUBERCLE BACILLUS.

FIFTY years ago last Thursday ROBERT KOCH showed the Physiological Society of Berlin the organism of tubercle which had until then eluded search. Others before him, especially COHNHEIM, had insisted that tuberculosis was a chronic infectious disease due to a specific organism, and the closely related lepra bacillus had already been discovered. Systematic botanists of the time, like v. NAEGELI, mocked at the part attributed to microscopic vegetable life in the causation of disease, regarding it as akin to the personification of the elements by primitive peoples. KOCH however brought the bacilli within range of his microscope lens by means of prolonged staining in alkaline methylene-blue and counterstaining with vesuvin which discharged the blue colour from all the tissue elements except the tubercle bacilli. He saw the blue rods first on a coverslip preparation of miliary tubercle accidentally left in contact with methylene-blue for 24 hours in an ammonia-laden atmosphere. He found that this peculiarity of being rendered visible by the combined action of methylene-blue and vesuvin was possessed only by the bacilli of tubercle and of lepra. Commonplace though that may now sound, this first essay in bringing out by staining methods differences between organisms otherwise so similar was, as our leader writer hazarded at the time, the inauguration of a new era in our knowledge of the ætiology of diseases and in the organisation of measures for their prevention.

ROBERT KOCH.

Now if KOCH had done this and no more than this, March 24th, 1882, would still be an important date. But, statesman that he was, he did not publish his discovery until he had found these blue-fast bacilli not only in recent miliary tubercles money no doubt will be required, and it should come, in large part, from health insurance companies and societies. At the present time the greater number of these make no direct contribution to the hospitals for the treatment of their members, relying on the ratepayer and private charity to supply this most costly service for them. They would in any case save much in sickness payments, for patients would recover more quickly and completely their full working capacity, the number of cases of so-called traumatic neurasthenia would decrease; county court actions would become fewer, for no patient could, and few would, wish to maintain they were unfit after a period of full work at the convalescent institution. A further contribution should come from local borough and county councils. Such an investment should yield a quicker return in good health than much of the money now spent, for instance, on tuberculosis; while the greater rate of turnover at the general hospitals would save the expense of adding to their existing number of beds. Finally, the patients themselves should pay something, however small; for it is human nature to undervalue benefits which come for nothing, and a small payment would be an incentive to take their treatment seriously.

Some may doubt perhaps how amicably municipalities and health insurance companies would work in double harness. Should they prove an awkward team, other methods of raising money might have to be devised. However established it would, we believe, soon appear that large convalescent centres are in the main an economical addition to the health services by completing the fine work now being done in the general hospitals.

ANÆMIA.

LECTURES seem to be coming into their own again. They were at one time occasions of moment; scholars and students were few and scattered with small opportunities of conversational intercourse; the printed word was occasional and copies scarce, so that lectures and discourses were the means by which learned men passed on their erudition to those who were curious enough to want to know. Their importance may be taken to have steadily declined during the nineteenth century, certainly in its second half. Their enormous increase along with the great extension of university teaching led perhaps inevitably to a decline in their quality, and it was often more pleasant and at least as profitable to get the information from the abundance of printed matter which had become available. But in the present century, and in the medical sciences especially in the last ten years, this print has become unmanageable and serious students may not know even where to look for the information they want, and hardly anyone who is personally involved in working in some small corner of his own has the chance as well as the inclination to know what is going on elsewhere. Lectures are therefore coming in again either to give an expert's views on some special topic or to suggest generalisations derived from varied fields, and if we may judge from the audiences which have lately gathered at the College of Physicians and elsewhere it certainly seems that London students, young and old, are coming to value good lectures more than they did a few years ago. We say good deliberately, for lectures now are not readings. The lecturer must needs have a tale to tell, but how he tells it matters quite as much as what he has to say. Whatever his particular technique, personality and sincerity are as desirable as orderly clarity. A good lecture seems indeed to have much the same qualities as a good sermon, and it would probably be idle to attempt any clear distinction between them.

Those who heard the Goulstonian lectures on the pathology and treatment of anæmia given lately at the Royal College of Physicians of London by Dr. L. J. WITTS, of Guy's Hospital, will we believe appreciate the reasons for the foregoing reflections. Those who read them in this and the preceding numbers of THE LANCET will do no more than recognise a singularly interesting account of a subject which has advanced greatly in recent years. It is not so long ago that there were only three sorts of anæmia—pernicious, chlorosis, and secondary. And if nothing fresh had since been added there would now be only two, for chlorosis has disappeared; we should dearly like to have it back for a while that it might be investigated by modern methods. It is possible, but sadly unlikely, that some cult of Victorianism among young unmarried women may bring it to light again. Dr. WITTS in fact does not mention it at all, which is perhaps why he also omits all reference to the distinction, made so clearly in chlorosis by LORRAIN SMITH, between anæmias due to an excess of plasma and those in which there is a real defect in the hæmoglobin of the erythron.

The most important contribution to our understanding of the anæmias is we think his attempt to bring together a whole series of apparently different conditions under the general heading of anæmia from defective nutrition or disordered assimilation, with the idea that some specific substance or substances are needed for each of the developmental stages of the normal red cell. We have on the one hand the simple nutritional anæmia so common in infants, which, as Dr. HELEN MACKAY has shown, is due to the low iron and mineral content of milk and can be cured by a mixed diet and inorganic iron salts; these supply the substances which are necessary for the proper maturation of normoblasts into normal erythrocytes. On the other hand there is Addisonian pernicious anæmia in which the stomach fails to secrete a ferment which produces from meat a substance, normally stored in the liver and kidneys, which is necessary for the development of megaloblasts into normoblasts; intestinal derangements which prevent the absorption of this substance may have the same effect when the gastric juice is normal. The due differentiation of the blood-cells is as it were blocked at a certain point and, as Dr. WITTS points out, the accumulation of iron in the liver and spleen is due not so much to excessive destruction of red cells as to the failure of the marrow to make use of the materials for making fresh red matters, for many medical men feel that they are in the same position, and require to give more intensive consideration to the different aspects of sex and family relations before their views should be allowed to influence the lives of others. For this reason it seems possible that of those seeking the bureau for assistance as many may be directed there by their doctors or their clergymen as will find their way there independently.

HEALTH OF THE NAVY IN 1930.

THE statistical report of the Health of the Navy for the year 1930,[1] the first to be signed by Vice-Admiral R. St. G. Bond, has just been issued. The total force was 88,840 (86,240 in the preceding year), marines at headquarters being included for the first time. The fresh cases were, per 1000, 428·08 (482·03), the invalids 12·55 (14·30), and the deaths 2·47 (2·94), all showing decreases. Important causes of loss of service were local injuries and wounds, acute gonorrhœa, and, with less loss, catarrh. The chief causes of invaliding (total, 1115) were pulmonary tuberculosis 202 (228), diseases of the eye 199 (170), diseases of the ear 91 (132), injuries 80 (105). Deaths were 220 (254), their chief causes being injury 94 (92), pneumonia 16 (21), pulmonary tuberculosis 13 (19), heart disease 13 (7), and diseases of the intestines 12 (15). There were no deaths from enteric this year or last, but 7 (12) from meningococcal infection. Of the deaths from injury, 39 (42) were due to drowning; there were 14 (9) suicides. Of cases of illness, 11 (5) were due to the enteric group, 383 (1661) to influenza, 388 (539) to malaria, 5 (14) to Mediterranean fever, 115 (179) to pneumococcal infection of the lung, 78 (100) to pyrexia of uncertain origin, 118 (128) to rheumatic fever, 47 (81) to sandfly fever, 1 (2) to small-pox (a slight case, sent back to duty in 19 days), 203 (240) to tuberculosis of lung, with 13 (20) unclassified. New venereal infections were 5154 (5342), a definite reduction. From the new tables we gather there were 5 cases of encephalitis lethargica; single cases are mentioned of blackwater fever, relapsing fever, tetanus, and of schistosoma from the Mediterranean, though none from China. The death-rate from disease (1·26) is the lowest hitherto recorded. The successful preventive measures in *Delhi* for her cruise up the Amazon (chiefly mosquito nets) are given in detail; no cases of malaria occurred. Of meningococcus infection the largest group was 6, from *Pembroke*, depôt-ship at Chatham. Eight years ago we observed[2] that there was no special notice taken of tuberculosis in the health reports of the Services, though the disease was causing them a loss of 721 men annually. Much attention has been paid to this subject meanwhile, but if we go back to the Navy Health Report for 1921, then current, and compare its figures with those for 1930, we see little evidence of improvement; there are indeed slightly more cases and more invalids.

Statistics of Tubercle in the Navy per 1000.

	Cases.	Invalids.	Deaths.
1921	2·36	2·23	0·28
1930	2·42	2·36	0·16

Tuberculous cases and invalids are almost, as we see, the same people, and as the Navy publishes a most useful list of the ages and length of service of all invalids, the distribution of cases in the service can be readily calculated. It emerges that since 1921 the distribution of cases has been changing. Half the men in the Navy have under 10 years' service, and half have more. In the years 1921–24 the tuberculous invalids of under 10 years' service averaged 123, those of over 10 years' service 71. In the years 1925–30 there were on an average 105 of under 10 years' service and 96 over. It would appear that the men on the whole are developing tubercle later in life. Either there is a greater risk of contracting tubercle in the Navy as service continues, or the improved hygiene of to-day strengthens the resistance of those fated by their childhood's experiences to develop tubercle and delays its appearance. The question certainly deserves discussion. It must not be forgotten that the death-rate for tubercle among men in England and Wales rises pretty regularly from age 15 to age 55, so these men are serving at the most susceptible ages, and that there is a school of medical opinion which holds that most of the tubercle of the Services has come into them from civil life. Of the great groups of the Service, marines, with 1·16 cases per 1000, were least attacked in 1930, seamen, with 2·49 cases per 1000, the most. There are fewer cases of venereal disease this year, though more days under treatment, but these are only a fifth of the total from all diseases and injuries; formerly they were a third. The long accounts of work being done in pathological and other laboratories have interest, but the first-hand clinical reports of cases and epidemics seen on foreign stations, the special characteristic of the old reports, are excluded to-day, which is a great loss. Much information of value was extracted from them in the Croonian lectures of last year. The note on diphtheria strongly supports the slogan, "Prevention pays!" The cases of diphtheria at Greenwich Hospital School used to cost about £1500 a year, but thanks to Schick-testing and immunisation there are now no cases; to maintain this condition costs but £30 a year or less. Reports from Malta support Ziemann's view[3] that leguminous crops which form coumarin are a great protection against malaria, and that it is their presence that protects Malta from malaria. At Haslar, which has 150 more beds this year, an electrocardiograph has been installed. The many mosquito-breeding places that surround the hospital are utilised for training surgeon-lieutenants in antimosquito work. The volume of dental work is continually increasing. There is still no mention of the health condition of the cadets at Dartmouth.

ANTIMENINGOCOCCAL SERUM IN CEREBRO-SPINAL FEVER.

THE scheme designed by the Ministry of Health[4] to determine the value of serum treatment during the present prevalence of cerebro-spinal fever has failed as yet to secure really useful records, and a new leaflet has been issued to medical officers of health explaining why. A particular object of the scheme was to compare the potency of different serums in current use. Through the courtesy of medical officers of health, hospital medical officers, and medical practitioners, over 300 individual case records have already been received; the variation in the methods of using the serum have made them difficult to compare. The doses of serum given, the period of the disease at which serum treatment was begun, and the time during which it was continued, have differed widely from the practice of serum but also within the giant cells, in the walls of tuberculous cavities, in the sputum of phthisical patients, in degenerated "scrofulous" glands, in "fungous" joints, and in the bones of tuberculous cattle. They were never absent in the granulomas produced by inoculation of tuberculous material even in animals of the most different species. More than this, he had already carried on an extensive series of cultural experiments which yielded striking results. Employing sterilised blood-serum from the ox as a medium, he had cultivated the bacillus from fresh miliary tubercles, and had kept some of these cultures going for 200 days. More than this, he had gone far to satisfy himself of the validity in the case of tubercle of the postulates for a specific infection which have since been known by his name. It is a curious and rather painful reflection that much of what Koch had actually discovered before he made his demonstration to the Berlin Physiological Society was overlooked by his successors, and was "rediscovered" afterwards in various research laboratories. In a commemorative address [1] Pfeiffer remarks that the intervening 50 years have added scarcely anything material to Koch's work. Having definitely established the parasitic nature of tuberculosis, Koch went on to consider whence the organisms came and how they got into the body. From the fact that the bacilli develop within a narrow range of temperature, roughly 30° to 41° C., he deduced that the organism is a true parasite, incapable of developing outside the body. He regarded the germs as entering the system by the inspired air, possibly adhering to the particles of dust which are carried along with it, and he discussed with great discernment what can be learnt from the fact that to render an animal with certainty tuberculous he had to insert the infective material into the subcutaneous tissue, the peritoneal cavity, or the anterior chamber of the eye, infection from the surface of a wound only occurring exceptionally.

[4] Review of Certain Aspects of the Control of Cerebro-spinal Fever (Ministry of Health Reports on Public Health and Medical Subjects, No. 65).

Koch's announcement spread over the prescient world with astonishing rapidity. It was on May 8th, 1882, only six weeks after the original communication, that Mr. Watson Cheyne demonstrated in the pathological laboratory at King's College, London, the bacilli brought over to England by Dr. Goltdammer, Koch's private assistant, when among the 70 people present were Lister, Wilks, Pye-Smith, and Beale. A culture of tubercle on blood-serum was shown on May 10th at the soirée of the Royal Society of London. Thereafter the tubercle bacillus soon became familiar to every medical student, not, it is true, in the original blue-brown method, but in the familiar garb of scarlet introduced by Ziehl and modified by Neelsen. It was a simple matter to try other mordants than potash, which was soon replaced by aniline water with gentian-violet, and then carbolic acid with fuchsin. To add only two scraps of history. It was Samuel West who first did routine tests for tubercle bacilli in sputum, at the Victoria Park Hospital. Vincent Harris, who was then remounting specimens of diseased lung in the museum of St. Bartholomew's Hospital, was able to demonstrate in sections, some of them 50 years or more old, the presence of tubercle bacilli almost every time. And so in every country Koch's teaching was a similar turning point in the relation of humanity to disease. Economic conditions in Germany have led to the postponement to 1933 of any large-scale jubilee celebration, but during the last week or two the chief general and special German medical papers have contained appreciative articles.

ANNOTATIONS

SEX EDUCATION

We publish this week a letter from the honorary medical secretaries of the British Social Hygiene Council announcing a departure on the part of the Council which may prove to be of wide utility. That many of the troubles arising in connexion with marriage would be prevented by greater physiological knowledge on the part of the contractors has been recognised by the medical profession for literally ages, and by a considerable proportion of thinking laymen for at least a century. To-day it has become universal knowledge, and a profuse literature is available for the public digestion purporting to give the necessary information. The quality of these books varies much, but far more of them are useless than useful, some are mischievous, and some are designed to bring the return in money earned by salacity. Knowing the unsatisfactory nature of many of these books, it is good to learn that the Council proposes to publish an authoritative manual dealing with the personal problems arising out of marriage, while they are also approving of an arrangement by which those in need of private advice can obtain the aid of the secretary general of the Council, at a bureau of consultation. The "Personal Problems" bureau will be under Mrs. Neville Rolfe in her individual capacity, and will be established on a commercial self-supporting basis, part of any profits accruing being given to the Council for its general purposes. We understand that the bureau is intended to have a larger scope than the consideration of difficulties incidental to marriage. Parents, for example, who may wish for assistance as to practical methods in the sex-training of their children will also be welcomed, and afforded advice of the sort that, for this reason or that, they no longer seek as a matter of course from the doctor or clergyman. With regard to the assistance of ministers of religion in settling questions of the sort, the report of a Lambeth Conference has now definitely stated what the public had for some time come to think—namely, that on such subjects as preparation for marriage admonitions could not be given by unmarried clergy with much chance of their being sensible. More than ever is this true now that the sex education and sex adjustment have been diligently studied as special subjects. It is not only clergymen, married or unmarried, who are unlikely to have at their disposal sufficient knowledge to give sound advice in such of infection and resistance. About three-quarters of adults in Melbourne have in their serum a substantial amount of antitoxin.[5] Of 91 new-born infants, 76 (83 per cent.) were similarly endowed, but only 10 of 51 children (20 per cent.) from 4 months to 2 years; the grown-up condition is reached at about 7 years. The tale is evidently the same as with diphtheria. The changes and chances of communal life lead to infections and subinfections which produce *an active immunity in the majority* of people, with or without any memorable illness. The human placenta being what it is, these antibodies are transferred from mother to fœtus and carry the infant through its first few months. They then fade away and the child is left to develop its own individual immunity.

DIPHTHERIA PREVENTION IN LONDON.

THE progress of active immunisation to diphtheria in the British Isles and in New York is recorded by Dr. J. Graham Forbes in an interesting section[6] of the annual report of Sir Frederick Menzies, medical officer to the London County Council, on other sections of which we have already commented. In Metropolitan and Greater London up to the end of 1930 a total of 35,835 children at welfare centres or in residential institutions, and 7552 members of the nursing staffs of hospitals, chiefly fever hospitals, had either been inoculated or were known to be immune—a grand total of 43,387. Corresponding figures for 1928 show that the numbers tested have been more than doubled since then, and those immunised have increased over two and a half times. Can this achievement, having regard to the size of the population of London and the incidence of diphtheria, really be regarded as satisfactory? In New York City, according to Dr. Forbes, the determined efforts of the public health authorities to control diphtheria have been developed as a carefully coördinated scheme which included all concerned in the care of children, and as a result the numbers of children now immunised have been increased by over 380,000 in 1929 and 1930. In 1930 in New York City there were 3794 cases of diphtheria with 198 deaths. Of the fatal cases only four patients had previously received protective inoculation, in two of them within a month before attack. In the County of London in the same year there occurred 13,361 cases of diphtheria with 455 deaths, an increase over the previous year of 1708 cases and 104 deaths. In the outer ring of Greater London during the same year 4506 cases of diphtheria occurred with 190 deaths. The County of London in 1930 experienced approximately the same incidence of diphtheria, although the fatal cases were considerably fewer, as New York City, in 1927, before the intensive campaign commenced. In that year there were 13,507 cases of diphtheria with 717 deaths in New York. In Metropolitan London, Holborn Borough Council, on the advice of its medical officer, Dr. C. W. Hutt, provided facilities for testing and immunisation as far back as 1922, and was followed by 13 other metropolitan boroughs at various dates from 1926 onwards. Two of these boroughs, Finsbury and Poplar, have closed their immunisation centres owing to lack of demand. Finsbury had the highest diphtheria attack rate—namely, 4·63 per 1000—in Metropolitan London in 1930. Poplar's rate was 3·67 per 1000, the London mean attack rate being 3·03 per 1000. The total numbers of children dealt with at some of these metropolitan borough clinics since their opening are lamentably small. In certain districts of Greater London, notably Heston and Isleworth, Wood Green, and Ilford, the prospects are much more cheering. Dr. E. H. T. Nash and Dr. Guy Bousfield recently described[7] the details of an immunisation campaign in Heston and Isleworth and its results. The great success of this work may be ascribed to propaganda devised upon the assumption *that the public to be influenced was intelligent*, and to great frankness. Care was taken to make no extravagant promises of success. The response exceeded expectations, and Dr. Nash and his colleague are to be congratulated upon the results of an active policy well devised and carried out. In the absence of effective propaganda and coördination of effort by all concerned in the welfare of children, active immunisation against diphtheria can hardly be expected to make the progress which it obviously does make wherever its value is properly presented to the public.

THE DIFFERENTIAL DIAGNOSIS OF PULMONARY TUBERCULOSIS.

THE complaint is often made that State interference in the treatment of tuberculosis has robbed the hospitals of the clinical material necessary for the instruction of students, and the general practitioner of interest in patients for whose care he has only a divided responsibility. The loss of the student and general practitioner has been the gain of the tuberculosis officer, whose special knowledge may compensate for the relative ignorance of his colleagues in districts where a close connexion is maintained between the practitioner's surgery and the officer's dispensary. The patient however must pass from the panel to the dispensary, and if the practitioner is not qualified to recognise the signs of incipient disease he may not come under the care of the tuberculosis officer till all hope of cure has vanished. Dr. Philip Ellman, realising the danger of the new situation, has written a book[8] designed to help the general practitioner who feels that he has lost touch with modern ideas on the subject of tuberculosis, and to bring his knowledge up to date. Dr. Ellman is concerned not with scientific theories, but with clinical observations, and his teaching is lucid and practical. He stresses the importance of radiology in the diagnosis of chest disease, and the numerous radiograms illustrating morbid conditions have been selected with discrimination and are well reproduced. The description of collapse therapy provides all that is necessary for an understanding of a valuable method of treatment, the carrying out of which must of necessity be left in the hands of those who have had special training. The chapter on the pulmonary diseases of childhood is less satisfactory. The practitioner to whom this book is addressed may be disappointed to find only 20 pages devoted to a subject that is beset with difficulties and which is of such vital importance to him. Though numerous references would be out of place in a work of this kind, a short bibliography would have added to the value of a book which is not a text-book dealing with the diagnosis, prognosis, and treatment of diseases of the chest as met with by the general practitioner, but a description of modern methods in the differential diagnosis of chronic pulmonary disease with special reference to pulmonary tuberculosis.

treatment as set out in the Review, which followed the original indications given by Flexner and many subsequent authorities. These authorities advocate lumbar puncture as soon as the disease is suspected, and the intrathecal injection of serum without waiting for bacteriological confirmation or typing. The doses should be about 30 c.cm. (or 10 c.cm. of concentrated serum) for adults, and only slightly less for older children; general anæsthesia increases the amount of cerebro-spinal fluid obtained, and hence the injection of full doses of serum without risk of increasing the intrathecal pressure. The injection should be repeated every 24 hours for three or four days, until convalescence is obviously established, and recommenced if relapse occurs. Though individual cases require exceptional treatment, any great divergence from accepted practice obviously reduces the value of case records collected for the purpose of assessing the therapeutic potency of the serum now available, and of contrasting the curative effect of one serum with another. Less than half of the records hitherto received show evidence of even approximate compliance with accepted practice. It is very desirable that the further case records furnished should, wherever necessary, be accompanied by some notes of the reasons which have seemed to make it impossible or undesirable in the particular case to give serum early enough, in sufficient doses, or sufficiently long to secure its full benefit. The case reported by Dr. Burton in our present issue emphasises both the message that long-continued treatment is required, and that treatment cannot always be on routine lines. The patient described, after being in hospital for more than 17 weeks, during which time he had two relapses, made a complete recovery, mental and physical, but not until 78 lumbar punctures had been performed and 2601 c.cm. of cerebro-spinal fluid removed. The serum seemed to have little specific action in this case. A variation of technique to meet special circumstances must obviously continue, but while this inquiry is in progress an obligation rests on medical men to adopt a scheme which will make their results comparable unless this is definitely contra-indicated.

CURABILITY OF CANCER OF THE STOMACH.

THE prognosis as regards cure of cancer of the stomach is poor, yet D. C. Balfour,[1] of Rochester, Minn., is able to present an analysis of 128 patients, operated upon between 1910 and 1920, who survived partial gastrectomy for ten years or more. It was found that the cancer was removable in 19 per cent. of the cases seen, and of those in which it was resected about 20 per cent. survived for at least ten years. A. J. Walton,[2] in a series of 62 partial gastrectomies, found that only four (including one case of sarcoma) survived four years or more in spite of radical operation, whereas in some of the cases reported by Balfour only a local excision was done, and of these six survived the ten-year period. The grading of the tumours in the 128 cases "cured" confirms the value of microscopical grading as an aid to prognosis and as an indication for resection. The site of the tumour has a marked influence on the possibility of removal. Lesions at the upper limit of the lesser curve are very unfavourable, and from the study of these 128 cases Balfour finds that lesions of the antrum are less favourable than those of the body, since in the pyloric region the lymph glands are extensive, early involved, and less easily completely removed. The delay in diagnosis is not to be attributed to the clinician but to the insignificance of the early signs and symptoms, and therefore one thorough radiographic examination is not sufficient and repeated examinations must be made if necessary. Apparent good health, a normal test-meal, no loss of weight, and no palpable tumour do not rule out cancer of the stomach. The general rule is that exploration should be carried out unless irremovable metastases can be demonstrated, and it is to be remembered that a large gastric tumour by no means contra-indicates operation. On exploration the uninvolved portion of the stomach above a large tumour may be rigid and thick, and this condition may wrongly lead the surgeon to decide against resection. Balfour considers that it is at times good practice to disregard involvement of the lymph nodes, since a patient may be cured even if all the involved glands are not removed. H. Hartmann, on the other hand, who reports 31 per cent. of three-year cures in 125 cases of gastrectomy, attributes his comparatively good results to his great care in removing those groups of glands most subject to invasion.[3] Balfour's last 200 cases of partial or total gastrectomy for cancer showed an operative mortality-rate of 5 per cent.

STAPHYLOCOCCAL INFECTIONS.

So many infections with staphylococci are of a comparatively trivial character that the capacity of these organisms for evil and the possibility of coping with them by serological methods have been rather overlooked. Staphylococcal septicæmia is not common but it is extremely fatal, the mortality being about 75 per cent., or even more. In the Bundaberg disaster 21 children were inoculated with a contaminated diphtheria toxin-antitoxin mixture and 12 of them died in a day or two from staphylococcal septicæmia. From this tragedy came Burnet's study [illegible] toxin and the preparation of an [illegible]. and his work has lately been re-examined and confirmed by Drs. H. J. Parish and Winifred H. M. Clark, at the Wellcome Laboratories at Beckenham.[4] The organism produces its toxin best in an atmosphere containing a good deal of CO_2, a cultural detail no doubt responsible for its toxigenic capacity having been overlooked for so long. The toxin is very poisonous to experimental animals; it is also conveniently hæmolytic so that it may be titrated in vitro as well as in vivo. Rabbits and horses may be immunised by a course of progressive doses either of the fresh toxin or of toxin which has been detoxicated with formalin. The sera thus prepared protect animals against fatal quantities of toxin, and they show some capacity to prolong the life, and sometimes prevent the death, of rabbits inoculated with live cultures; in this respect, however, there is obviously room for improvement. It seems likely that the leucocidin to which Drs. P. N. Panton and F. C. O. Valentine drew attention in our issue of March 5th (p. 506), and which is distinct from the hæmolytic toxin, needs neutralisation too, and this is no doubt within the possibilities of serum therapy. Bacteriologically the problem has a fruitful appearance, and it is to be hoped that adequate clinical trial will be made of the sera which are available, and of the active immunisation with toxoid which has been briefly explored at the London Hospital.

This renewed interest in staphylococci has also contributed useful information on the natural history

SPECIAL ARTICLES

PULMONARY TUBERCULOSIS IN CHILDHOOD.

BY F. J. BENTLEY, M.D. DURH., M.R.C.P. LOND., D.P.H.,

DIVISIONAL MEDICAL OFFICER, LONDON COUNTY COUNCIL.

ATTENTION has been focused of late on pulmonary tuberculosis in the child, expecially of school age, and in some quarters there is a feeling that study in this direction may go far to solve the problem of adult tuberculosis. In this connexion two questions spring to mind. Firstly, does indeed the tuberculous child grow up to help to fill our sanatoriums in adult life? Secondly, is the "A," or negative sputum, case in childhood of great importance, or can we afford to pay less attention to this and concentrate on the "B," or positive sputum cases?

The London County Council records show that out of the 4189 pulmonary and non-pulmonary patients coming under treatment for the *first time as adults* during the year 1930 only 25 were known to have received treatment under the Council's scheme for pulmonary tuberculosis during childhood. Of these 25, 11 were definitely positive sputum cases when treated as children, and all except one of the remainder showed undoubted involvement of lung tissue though tubercle bacilli were not demonstrated in the sputum. Looking at the question from another angle, it is significant that the after-histories of children with positive sputum are markedly different from those who do not cough up tubercle bacilli. Thus, taking the "A" cases who were discharged from treatment in 1924, we find 92·9 per cent. alive and well at the end of five years, whereas at the end of the same period only 15 per cent. of the "B" children were still surviving.

These figures are mentioned not by any means as exhaustive, but they do indicate that the disease that causes such concern in adult life occurs for all practical purposes de novo, and that clinical tuberculosis in the child is but little related to it. Also that "A" cases generally in childhood do very well, and that those indefinite cases that are, perhaps still too often, notified as suffering from pulmonary tuberculosis need cause little alarm.

The positive sputum cases in childhood are, on the contrary, very grave, and it is well to consider their occurrence and to ponder if more can be done to detect them earlier, or, better still, to prevent them.

Every year in London there are about 60 applications for residential treatment of such children below the age of 16, the great majority being new cases. These represent practically all the new cases coming on to the dispensary registers; during 1930 only three additional cases were known to the dispensaries for which residential treatment through the Council's tuberculosis scheme was not sought. The incidence in London as shown by the actual number of deaths recorded is as follows:—

Deaths from Pulmonary Tuberculosis. London, 1930.

Age-group.	Males.	Females.	Total.
0–5	20	17	37
5–10	8	9	17
10–15	14	27	41
0–15	42	53	95

These figures may include a few negative sputum cases and some cases especially below the age of 5, in which the diagnosis may have been in doubt, but the majority must have been positive sputum cases.

An Investigation.

It will be seen that this condition is fortunately very rare. With the willing help of the metropolitan borough tuberculosis officers and the London County Council school medical service, it has been possible, however, to survey a group of 48 consecutive cases of pulmonary tuberculosis with positive sputum occurring before the age of 16. Certain factors have been analysed.

Sex.—There were 36 (75 per cent.) females and 12 (25 per cent.) males. This female preponderance is in accord with the excess of girl sufferers, chiefly above 12 years of age, which is constantly seen throughout the world.[1] My figures, however, indicate a more striking contrast than is actually the case as shown by the death-rates from tuberculosis for the whole of England and Wales.

It has been thought that the greater strain of puberty and adolescence in the female accounts for a good deal of this increased incidence, but whilst it has been popular to speak of this "strain" in many connexions, it has not been decisively demonstrated and possibly it is not important. The health officer of Calcutta in his report[2] for 1929 says that five girls die from tuberculosis between the ages of 10 and 20 for every boy; he insists that the most important factor in the ætiology of this disease in young girls in India is early marriage with its accompanying strain; but the predominance of the disease in females in England starts in the 5–10 year age-period. It may be that the closer contact that usually exists between female children and the other members of the family gives rise to greater possibilities of infection, or explanation may be found in the girls of this age already doing housework and generally not being so much in the open air as the boys.

Age.—As regards age at notification, one case in this series was 7 years of age, but, excluding this, the youngest was 10, whilst the average age at onset was 14; 64 per cent. of all the children were 14 or more. It will be seen, therefore, that half the cases are first diagnosed *after* leaving school.

Previous illnesses and mode of onset.—These children had mostly suffered (together with the majority of their school-fellows) from the specific infectious fevers, and had commonly had measles, whooping-cough, scarlet fever, bronchitis, &c. Cough and lassitude were the initial symptoms most frequently noted. It is interesting to learn from the school medical histories that some of these children were apparently healthy and robust before the onset of their symptoms. Some were apparently perfectly fit until the week or two before notification of the disease; two were keenly engaged in athletic pursuits, including swimming. It has been shown that there is no co-relation between tuberculous infection as determined by the tuberculin test and diminished body-weight[3]; recent work in America suggests that the influence of malnutrition generally has been overrated.[4] We must look therefore for the earlier cases of this disease just as much amongst those who are apparently healthy as amongst those who are debilitated.

Delay between onset of symptoms and diagnosis.—In over half the cases the period between onset of obvious symptoms and diagnosis was less than eight weeks. In only nine cases was there more than three months' delay. It is well known how loth many people are to consult a doctor when ill-health is first noticed. Generally we must consider that as soon as these

THE VALUE OF INTRACARDIAC INJECTIONS OF ADRENALIN.

THE efficacy of adrenalin injection into the heart in asphyxia has recently been disputed. Sir E. Sharpey-Schafer, F.R.S., and Mr. W. A. Bain describe[1] experiments on cats designed to test the value of such injections. A simple asphyxia was produced by occluding the trachea, the animals being anæsthetised with urethane. It was sometimes possible to revive the animal after the circulation and respiration had ceased by artificial respiration, provided the interval had not been too prolonged, though mere renewal of the air in the chest through a tracheal tube might have no effect. It was shown that where this latter procedure had failed, intracardiac injection of adrenalin quickly caused the heart to beat again. The blood pressure rose rapidly from zero to high levels, and then natural respiration was resumed. The recovery is attributed by the authors to the stimulating action of the adrenalin upon the arrested heart. Blood is pumped through the aerated lungs, and the asphyxiated bulbar centres are restored to their normal condition. The drug also acts upon the arterioles, and it is their contraction which causes the high blood pressures observed, and maintains the pressure at a sufficient level. These striking effects are most rapid if the injection is into the myocardium; if it is into one of the heart cavities they are produced more slowly, as the adrenalin then has to traverse the aortic and coronary systems—and if into the right heart the pulmonary system in addition—before it reaches the heart muscle. It was shown that in rare cases an adrenalin effect can be obtained with heart massage and artificial respiration without an actual injection. This appears to be due to the passage towards the heart of adrenalin-containing blood which has stagnated in the suprarenal veins in consequence of the failure of the circulation, and as a result of the intermittent pressure applied to the thorax and abdomen becomes driven to the heart. The work gives clear confirmation of the value of adrenalin as a stimulant to the heart and to the whole vascular system.

NAKED AND UNASHAMED.

A LETTER appears in last Saturday's *Times* pointing out that "active air-bathing" is extremely beneficial to the health and happiness of the indoor worker. The 22 signatories urge that the movement in its favour needs to be rescued from the ill-informed scorn and disrepute from which it has suffered, and that air-bathing should be raised to the level of other healthy recreations. There should be the same liberty with regard to clothing (away from the public highway) as is now allowed on the stage; "public authorities could well set aside grounds for air-bathing exercises; private people could well make similar use of their own grounds; light and air sports clubs could be founded, and so on."

On first consideration, the idea of a community of people deliberately practising nudity, especially with municipal encouragement, strikes the average person as somewhat ridiculous. Arguments commonly advanced are that nakedness is practised by savages, not by civilised races; that most people are ugly when stripped of their clothes; that nudity is indecent, and when practised between the sexes inevitably leads to promiscuity. But the discovery that the rays of the sun on the skin exert a beneficent effect on health has done something to undermine these prejudices. The thought of tuberculous children, now brown-skinned and active, tumbling about in Alpine snows is no longer disturbing, nor even the prospect of adults doing these things, as long as they are done for the sake of health and as long as the sexes are segregated. On the Baltic coasts public opinion is even more advanced, and nobody seems to be revolted by the spectacle of mixed bathing without garments of any kind. In England, however, most people would still regard such practices by civilised adults as barbarous and indecent. Not long ago Mr. Parmelee[1] attempted to expose the reasons for this condemnatory attitude. As is well known, anthropologists declare that it is suggestive dissimulation which is sexually exciting, not nudity, and what the anthropologist deduces from his studies, medical men and women learn from the more convincing process of personal experience. It is difficult to know to what extent perversions such as exhibitionism and scoptophilia are conditioned by the concealments of the body which are imposed by convention and by the mysteries and taboos it enjoins. Th major and minor neuroses which appear in civilise communities are now being thought of more an more in terms of repression, and it is argue to-day that many of these repressions can be averte by educating children differently, particularly i their early years. It is quite possible that a chang of attitude towards the body—one's own body an other people's—such as is implied in the disseminatio of gymnosophic ideals, might, without the leas harm to society, do much to dissipate superfluou and injurious repressions. Certainly the publi exposure of the body, undefended by clothes and th dignities of rank which they indicate, is an urgen inducement to physical perfection. And although th signatories of the *Times* letter may long for offici recognition inland, they are obviously fighting winning battle along our coasts each summer.

Lord Dawson has been re-elected president of t Royal College of Physicians of London.

Sir Henry Dale, F.R.S., has been reappointed member of the General Medical Council on t nomination of the Crown.

WE regret to announce the death, on Wednesda of Dr. R. M. Bronte, well known for his work connexion with medico-legal cases. He was path logist to Harrow Hospital and the Samaritan Fr Hospital for Women.

---

[1] *Nudity in Modern Life.* By Maurice Parmelee. Londo Noel Douglas. 1929. Pp. 303. 12*s.* 6*d.*

DOWN COUNTY MENTAL HOSPITAL: NEW PHYSI THERAPEUTIC DEPARTMENT.—The mental hospital at Dow patrick has always been one of the foremost in Ireland, and its convenient block-system design, its separate reception h pitals, and its occup [illegible] has now be added an up-to-dat [illegible] he new buil ing was opened on [illegible] r of Northe Ireland and the Duchess of Abercorn. Its equipme includes carbon arc and mercury-vapour lamps, a Sch pantostat, a vario-frequency diathermy machine, Vic and Aix douche massage baths, needle and spray bat Plombières douche, and full X ray outfit and dark roo The Governor switched on the dynamos and opened t new department with a gold key, and the Duchess then opened an extension of the occupational therapy department, where weaving, basket-making, rug-making, and art work of all kinds are to be provided for patients who are unsuited for work on the estate or in the workshops.

Of these children under survey, 42 per cent. belonged to families that had already shown at least one previous case of tuberculosis. This information about contacts was not considered sufficiently accurate, and special inquiry has been carried out to ascertain whether the contact in these cases has been with a non-pulmonary case or with a pulmonary case and, if the latter, whether the first case in the family was coughing up tubercle bacilli or not and whether living or dead, and 73 further cases have been investigated in this particular direction. The additional cases have occurred consecutively with each other and with the original 48. No selection has been made beyond the fact that all the children were sputum-positive cases of tuberculosis.

Analysis of these 121 cases shows that in 53 (44 per cent.) there was a history of a previous case of tuberculosis (pulmonary or non-pulmonary) in the household, but I will confine myself to a consideration of contact only with definite cases of pulmonary disease, alive and known to the dispensaries and presumably notified, and with cases that had died from this disease within the preceding five years. But before doing so I want to indicate approximately in how many school-children one might expect "normally" to find a history in the family of either notified living pulmonary tuberculosis or death from the disease within five years.

I wish to make it clear at this point that an accurate statistical survey is not being attempted here, and that such figures as I use now are put forward only to show the general trend of the argument.

At the end of 1929 in London there were 32,117 cases of pulmonary tuberculosis on the registers of the metropolitan boroughs. The total population was 4,417,900. There was therefore, one living case of notified pulmonary tuberculosis for every 137 people. From the 1921 census it is seen that out of a total London population of 4,484,532 there were 1,120,897 private families. Taking either a borough in which the children are all elementary school-children, such as Bermondsey (total population 119,452; total private families 28,610) or a densely populated borough such as Stepney (total population 249,657; total private families 55,832), and after taking into consideration the childless marriages and the single people living alone we cannot average more than five persons per family; it may be assumed, therefore, that throughout London there will be found one notified case of pulmonary tuberculosis in $\frac{137}{5}$ families; or, to put the matter another way, if we search the families of any 27 unselected elementary school-children, we may expect to find one living case only of notified pulmonary tuberculosis.

To include the possibility of history of death from pulmonary tuberculosis, it becomes necessary to add to the total number of living cases with which contact was possible the numbers of those who died from this disease during the years in which such history is to be taken into consideration. If we consider a family history of death from pulmonary tuberculosis within five years to be important, we must add 20,000 (five years × 4000 deaths per year) to the number of possibilities. The London population then would have 52,000 (32,000 + 20,000) "chances" of contact with a case of pulmonary tuberculosis, either alive and notified, or dead within the past five years—i.e., one in 85 $\left(\frac{4,417,900}{52,000}\right)$.

Thus one might expect to search the families of 17 $\left(\frac{85}{5}\right)$ school-children before finding either a case of notified pulmonary tuberculosis or history of a death from this condition in the preceding five years.

Converting these "normals" into percentages and comparing them with the incidence of previous pulmonary tuberculosis amongst the families of my 121 sputum-positive children, we find that, whilst 3·7 per cent. of normal school-children have in the family a living notified case of pulmonary tuberculosis, 14 per cent. of sputum-positive children show a similar family history; and whilst 5·9 per cent. of normal children have a case of notified pulmonary tuberculosis alive in the family or one dead within the preceding five years, 28·9 per cent. of sputum-positive children show similar contact with the disease. These contrasts are even more marked if the actual numbers of cases in the families of the affected children are taken into account, as in several families there had been more than one previous case of pulmonary tuberculosis either alive or recently dead.

It will be seen therefore that children from tuberculous households are specially liable to develop sputum-positive pulmonary tuberculosis.

Special Investigation of Contacts.

It becomes necessary now to consider what further can be done by specially investigating all such child contacts. It would mean a considerable work; would it be worth while?

Before answering this question let us see what is being done elsewhere. The work of Opie[7] and his colleagues in the United States is now generally familiar to tuberculosis workers in this country, and elsewhere in America similar intensive investigations by means of skin-testing and radiography on large groups of school-children have been carried out, as in Massachusetts[8] and in Chautauqua County, New York.[9] The Americans have not confined themselves to investigating contacts, but have combed through entire school populations, and they appear to think the results justify such a course, a large number of hitherto unsuspected children being found to be suffering from pulmonary tuberculosis either active or "latent."

It would appear therefore that more is being done in some parts of America with the help of tuberculin testing and radiography to find earlier cases of tuberculosis in children than we are doing in London, and it has been suggested by certain authorities that similar work should be started in this country.[10] [11] But the problem of tuberculous children in the States is very different from our task here. One point is fundamental and must not be lost sight of. Our children largely leave school at age 14, when there is very little serious tuberculosis to be found; above that age the incidence curve climbs steadily and steeply into the twenties; every year of adolescence provides an increasing number of cases. American "children" stop at school commonly until 16 years of age, and many of the high-school pupils are 17 and 18. At these latter ages tuberculosis becomes comparatively common, and the Americans find it. They find, in addition, many cases of so-called "latent" tuberculosis of uncertain significance. There is a real danger in labelling too many children as "suffering from" tuberculosis. We must not forget that there is a process of tuberculisation through which most children in our present civilisation have to pass.

How many real cases of pulmonary tuberculosis could we expect to find by investigating school-children in the "American" fashion? No group of school-children would provide more fruitful material than girls at school-leaving age who were contacts of either a living case of tuberculosis or in whose family there had been a recent death from the disease. I have said that one child out of 17 could be expected to fall into this group; out of 28,000 girls (school leavers in one year) of 14 years of age, a group of about 1600 "contacts" would be chosen. Now, whether we find them early or late, there are about 60 positive sputum children every year. Let us say that 45 of these are girls; let us say that 15 of these will be contacts; let us assume that all the sputum-positive children to be found cases show obvious ill-health, they are diagnosed quickly. As regards the *actual stage* (L.C.C. classification) reached by the disease when these cases were notified, 6 (13 per cent.) were B1, 31 (64 per cent.) were B2, whilst 10 (21 per cent.) were B3 cases. One case did not show tubercle bacilli when first notified and treated, but these were found on subsequent treatment in 1929 and again in 1930. In about three-quarters of these cases therefore, in spite of the short period of "delay," the disease had become moderately or hopelessly advanced before being diagnosed.

Present Organisation for Detection of the Disease.

In the London County Council schools, in addition to the routine medical inspections and the "specials," particular attention is paid to the contacts of cases of tuberculosis that are referred by the tuberculosis officers. The school medical and tuberculosis dispensary services between them form a network through which the whole school population has to pass, and in the case of "suspected" or "suspicious" children the net is kept very tightly drawn. Yet, in spite of this, an occasional case slips through. In considering reasons for this, we must not forget that many of these children had already left school. The possible very rapid spread of disease is also a factor. It is probable that some children develop into advanced cases in the matter of a very few weeks.

Another explanation of this occasional "missing" of early cases may be found in the very fewness of such cases. Very many physicians have never seen a child with positive sputum. The disease in children is so rare that even a tuberculosis officer may go right through a year without coming across a new case. When a bird is seen on the treetops it is a hundred times more likely to be a sparrow than a nightingale, and on the hundredth occasion the nightingale is likely to be passed over as yet another sparrow; similarly, it is not to be wondered at that tuberculosis with positive sputum in childhood, from the very fact that it is such a rare bird, passes sometimes unrecognised—at least until the bird sings out.

Yet another reason why some early cases slip through is that physical examination for pulmonary tuberculosis is frequently misleading, and that in many cases it is only possible to arrive at a diagnosis after an X ray examination. Apparently healthy children, with no obvious abnormal physical signs, may show a considerable degree of involvement of the lung on a radiographic film. Dr. Burton Wood says,[5] "Without X ray control, physical examination is inadequate, for X rays have proved beyond all peradventure how slender may be the connexion between physical signs and pathological conditions."

Theoretically it is possible, then, that some of these cases could have been diagnosed earlier if, because of certain suspicions, physical or historical, the children had been subjected earlier to X ray examination. It is always easy, however, and seldom helpful, to be wise after the event, and it could be said with some truth that it is quite impracticable to radiograph every child who shows suspicious symptoms or history. Symptoms, when present, of early tuberculosis are, as we have seen, unfortunately not at all specific to that disease; excessive fatigue is frequently the only complaint, and this, of course, may point to very many other conditions besides tuberculosis. Clearly to radiograph every such child means radiographing almost all children. Short of this, is it possible to indicate any group of children who would, in the result, repay such special examination? Has this disease any specially increased incidence in any group of children to which we can point?

Contact with Infection.

Consideration of this brings us again to the question of "contacts." Attention has been drawn to the special care paid to children who are household contacts of notified cases of tuberculosis; the scheme whereby such contacts may be actually "boarded-out" with foster-parents is familiar; why such schemes and precautions? To some extent because the medical profession generally feel that children living in close contact with advanced cases of tuberculosis are liable to infection and disease, to some extent because the lay public is quite sure that consumption is "catching." There is much evidence, however, indicating that whilst tuberculosis is a bacterial disease, infection, when it occurs, does not determine the onset of the illness; the germ is widespread, yet comparatively few develop the disease; the result of examination of all contacts of all notified cases of tuberculosis is very disappointing, that is to say, very few new cases of the disease are found amongst those people who should be most subjected to infection.

Prof. Saugman was unequivocal about this problem. He stated: "It is not dangerous for healthy adults to be coughed at by patients suffering from pulmonary or laryngeal tuberculosis."[6] This may be true (though I, personally, prefer not to risk it!), but can we say the same of children? Can infection be unimportant in the adult and yet important in the child? It is so in some other diseases. Adults may mix, with but little risk of infection, with cases of measles and chicken-pox, but children will find these diseases readily transmitted to them. It may be said that adults have probably had chicken-pox or measles and thereby have gained an immunity, whilst the child is yet virgin soil. In many ways is not tuberculosis analogous?

Pathological investigations and tuberculin reactions have repeatedly shown that few humans reach adult life without becoming infected with the tubercle bacillus. In children, however, the factors are entirely different; practically speaking, all children are born without tubercle bacilli in their bodies—their resistance has not yet been tested. They may be exposed early, and succumb to the first breath of infection, as, for example, an infant who, from contact with an open case of tuberculosis, gets generalised tuberculosis and dies, frequently with meningitis; they may not be exposed to any definite source of infection and may become tuberculised very gradually as they grow up without any untoward effects; or they may be kept, in the minority of cases, entirely free from tubercle bacilli. All variations are seen between early and massive tuberculisation followed by death, and gradual tuberculisation without symptoms and with subsequent resistance.

The late Sir William Osler drew the parallel between infection in tuberculosis and the parable of the sower, which illustrates effectively the importance of the individual resistance and the importance of the virulence of the bacilli. Always there are the two determining features, the soil and the seed; but I venture to suggest that whilst in adults the soil is paramount, the seed already having been sown, in children we must consider, much more, the seed. In other words, whilst in adults we may afford somewhat to neglect infection as determining the onset of tuberculosis, in children we must pay it no little respect. Childhood is the time of preparation of the soil, and during that time we must beware of the seeds that are sown.

Of these children under survey, 42 per cent. belonged to families that had already shown at least one previous case of tuberculosis. This information about contacts was not considered sufficiently accurate, and special inquiry has been carried out to ascertain whether the contact in these cases has been with a non-pulmonary case or with a pulmonary case and, if the latter, whether the first case in the family was coughing up tubercle bacilli or not and whether living or dead, and 73 further cases have been investigated in this particular direction. The additional cases have occurred consecutively with each other and with the original 48. No selection has been made beyond the fact that all the children were sputum-positive cases of tuberculosis.

Analysis of these 121 cases shows that in 53 (44 per cent.) there was a history of a previous case of tuberculosis (pulmonary or non-pulmonary) in the household, but I will confine myself to a consideration of contact only with definite cases of pulmonary disease, alive and known to the dispensaries and presumably notified, and with cases that had died from this disease within the preceding five years. But before doing so I want to indicate approximately in how many school-children one might expect "normally" to find a history in the family of either notified living pulmonary tuberculosis or death from the disease within five years.

I wish to make it clear at this point that an accurate statistical survey is not being attempted here, and that such figures as I use now are put forward only to show the general trend of the argument.

At the end of 1929 in London there were 32,117 cases of pulmonary tuberculosis on the registers of the metropolitan boroughs. The total population was 4,417,900. There was therefore, one living case of notified pulmonary tuberculosis for every 137 people. From the 1921 census it is seen that out of a total London population of 4,484,532 there were 1,120,897 private families. *Taking either a borough in which* the children are all elementary school-children, such as Bermondsey (total population 119,452; total private families 28,610) or a densely populated borough such as Stepney (total population 249,657; total private families 55,832), and after taking into consideration the childless marriages and the single people living alone we cannot average more than five persons per family; it may be assumed, therefore, that throughout London there will be found one notified case of pulmonary tuberculosis in $\frac{137}{5}$ families; or, to put the matter another way, if we search the families of any 27 unselected elementary school-children, we may expect to find one living case only of notified pulmonary tuberculosis.

To include the possibility of history of death from pulmonary tuberculosis, it becomes necessary to add to the total number of living cases with which contact was possible the numbers of those who died from this disease during the years in which such history is to be taken into consideration. If we consider a family history of death from pulmonary tuberculosis within five years to be important, we must add 20,000 (five years × 4000 deaths per year) to the number of possibilities. The London population then would have 52,000 (32,000 + 20,000) "chances" of contact with a case of pulmonary tuberculosis, either alive and notified, or dead within the past five years—i.e., one in 85 $\left(\frac{4.417.900}{52.000}\right)$.

Thus one might expect to search the families of 17 $\left(\frac{85}{5}\right)$ school-children before finding either a case of notified pulmonary tuberculosis or history of a death from this condition in the preceding five years.

Converting these "normals" into percentages and comparing them with the incidence of previous pulmonary tuberculosis amongst the families of my 121 sputum-positive children, we find that, whilst 3·7 per cent. of normal school-children have in the family a living notified case of pulmonary tuberculosis, 14 per cent. of sputum-positive children show a similar family history; and whilst 5·9 per cent. of normal children have a case of notified pulmonary tuberculosis alive in the family or one dead within the preceding five years, 28·9 per cent. of sputum-positive children show similar contact with the disease. These contrasts are even more marked if the actual numbers of cases in the families of the affected children are taken into account, as in several families there had been more than one previous case of pulmonary tuberculosis either alive or recently dead.

It will be seen therefore that children from tuberculous households are specially liable to develop sputum-positive pulmonary tuberculosis.

Special Investigation of Contacts.

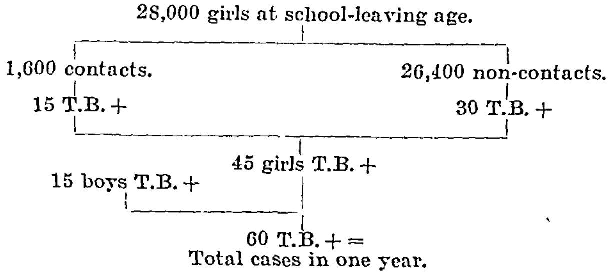
It becomes necessary now to consider what further can be done by specially investigating all such child contacts. It would mean a considerable work; would it be worth while?

Before answering this question let us see what is being done elsewhere. The work of Opie [7] and his colleagues in the United States is now generally familiar to tuberculosis workers in this country, and elsewhere in America similar intensive investigations by means of skin-testing and radiography on large groups of school-children have been carried out, as in Massachusetts [8] and in Chautauqua County, New York.[9] The Americans have not confined themselves to investigating contacts, but have combed through entire school populations, and they appear to think the results justify such a course, a large number of hitherto unsuspected children being found to be suffering from pulmonary tuberculosis either active or "latent."

It would appear therefore that more is being done in some parts of America with the help of tuberculin testing and radiography to find earlier cases of tuberculosis in children than we are doing in London, and it has been suggested by certain authorities that similar work should be started in this country.[10 11] But the problem of tuberculous children in the States is very different from our task here. One point is fundamental and must not be lost sight of. Our children largely leave school at age 14, when there is very little serious tuberculosis to be found; above that age the incidence curve climbs steadily and steeply into the twenties; every year of adolescence provides an increasing number of cases. American "children" stop at school commonly until 16 years of age, and many of the high-school pupils are 17 and 18. At these latter ages tuberculosis becomes comparatively common, and the Americans find it. They find, in addition, many cases of so-called "latent" tuberculosis of uncertain significance. There is a real danger in labelling too many children as "suffering from" tuberculosis. We must not forget that there is a process of tuberculisation through which most children in our present civilisation have to pass.

How many real cases of pulmonary tuberculosis could we expect to find by investigating school-children in the "American" fashion? No group of school-children would provide more fruitful material than girls at school-leaving age who were contacts of either a living case of tuberculosis or in whose family there had been a recent death from the disease. I have said that one child out of 17 could be expected to fall into this group; out of 28,000 girls (school leavers in one year) of 14 years of age, a group of about 1600 "contacts" would be chosen. Now, whether we find them early or late, there are about 60 positive sputum children every year. Let us say that 45 of these are girls; let us say that 15 of these will be contacts; let us assume that all the sputum-positive children to be found (including those who would normally be diagnosed at the later ages of 15 and 16) can be found in this age-group of 14, then we will "discover" 15 cases in 1600 children. As the assumption of finding all sufferers for that year at age 14 could, of course, not hold good, a much smaller number of children with disease would be found, and some of these would be discovered in the ordinary way by the methods and organisations at present at our disposal. Also, and *this is very important, two-thirds of the problem*—i.e., non-contacts—would remain untouched.

It is interesting to show the possibilities as below, for it also demonstrates the greater risk to contact children.



It is, of course, realised that a certain additional number of cases of pulmonary tuberculosis not showing tubercle bacilli would also be disclosed by such an investigation. Nevertheless, the number of sufferers discovered would be small. Investigate as we will we cannot find cases that do not exist.

Such investigation, therefore, hardly appears to be within the scope of the antituberculosis scheme of local authorities. Work of this description, however, should prove a fruitful source of research, as systematic examination of a group of specially susceptible children as indicated could not fail to reveal factors of importance. Children would be found apparently *normal at the time of investigation* who would develop definite sputum-positive disease subsequently; working backwards, then, to the original findings should, in certain cases, be the means of shedding light on equivocal factors and increasing knowledge about the earliest manifestations of the disease.

Summary.

(1) 48 consecutive sputum-positive cases of tuberculosis in children have been investigated with regard to, inter alia, the previous history and mode of onset, the period of delay between onset and notification, the exact stage reached by the disease at the time of notification, age and sex.

(2) 121 consecutive sputum-positive cases of tuberculosis in children have been investigated especially to ascertain the importance or otherwise of contact with other sufferers in the household. (These cases include the previous 48 children.)

(3) The present organisation for dealing with the problems concerned has been surveyed, and modern methods in operation in some parts of America have been discussed.

Conclusions.

A. Negative Sputum Cases.—(1) The great majority of negative sputum or "A" cases of pulmonary tuberculosis in childhood are alive and well after five years. (2) These cases only exceptionally develop clinical tuberculosis in adult life.

B. Positive Sputum Cases.—(3) The positive sputum cases of the disease in childhood are very rare. (4) When tubercle bacilli appear in the sputum of a child the outlook is grave. (5) Girls are affected much more frequently than boys. Whilst the appearance of positive sputum disease in any child under 16 years of age is rare, the condition below the age of 10 is a medical curiosity. The incidence rises with advancing adolescence, the curve ascending to the young adult peak in the twenties. (6) Children living in contact with open cases of tuberculosis in the household are in greater danger of developing the disease than children in healthy homes. (7) Children show a high degree of resistance to tuberculosis, as even child contacts, though they may show "infection" by tuberculin tests, seldom become affected by the disease. (8) When symptoms become obvious the disease is usually detected quickly. (9) The disease may be present for some considerable time, occasionally in apparently robustly healthy children, before symptoms proclaim themselves. (10) Even repeated physical examinations during this latent period fail frequently to demonstrate the trouble whilst it might be yet curable. (11) Radiography should succeed in some cases where ordinary methods of examination fail, and it should be employed in all cases where the suspicion of tuberculosis has been raised, before arriving at a negative diagnosis. (12) Suspicious symptoms, such as cough or lassitude, in a contact, especially in the older girls, should be the signal for an immediate and searching investigation. (13) Intensive investigation by means of systematic skin-testing and radiography on large groups of children on the *American lines* cannot be advocated generally in England. In a specially selected group of contact children, however, such work would prove a valuable research.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

THE following appointments are notified: Surg. Lts. J. A. Browne to *Gnat;* and A. E. Flannery to *Tarantula.*

ROYAL ARMY MEDICAL CORPS.

Maj. J. A. Whitaker, Dental Surg., relinquishes his temp. commn.

H. C. M. Walton to be Lt. (on prob.) and is secd. under the provisions of Art. 213, Royal Warrant for Pay and Promotion, 1931.

ARMY RESERVE OF OFFICERS.

Lt. W. F. Roper resigns his commn. and retains the rank of Lt.

TERRITORIAL ARMY.

Col. H. H. C. Dent, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

Capts. W. Barclay and J. F. O'Grady to be Majs.

Lt. E. C. Woodhead to be Capt.

E. Walsh to be Lt.

RESERVE OF AIR FORCE OFFICERS.

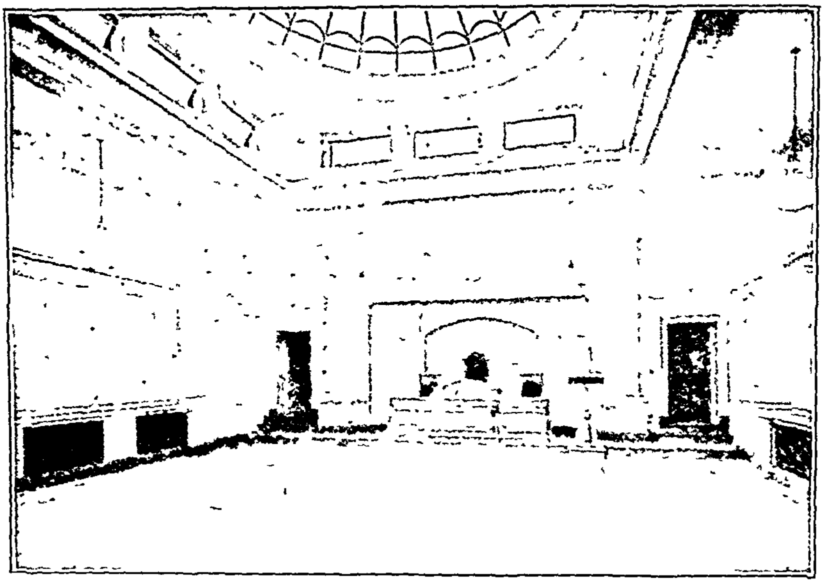
The undermentioned Flight Lts. relinquish their commissions on completion of service: *B. Pollard and G. J. Griffiths.*

OPENING OF MANSON HOUSE.

THE NEW HOME OF THE ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

MANSON House, the new home of the Royal Society of Tropical Medicine and Hygiene, was opened by H.R.H. the PRINCE OF WALES on March 17th.

Dr. G. CARMICHAEL LOW, President of the Society, in welcoming the Prince, welcomed also Sir Austen Chamberlain, who had helped the original appeal for funds in memory of the Father of Tropical Medicine, and so made possible the acquisition of Manson House. The Society, he said, had been founded in 1907 in order to centralise the various tropical medical activities both at home and abroad, and to give medical men who had worked in the tropics a place where they could meet and discuss their problems. The Society now had over 1700 Fellows, and more than 100 branches, all over the world. Its membership included representatives of medical, veterinary, and other sciences, and of practically every nationality, and by 1930 the Society had reached such dimensions that it was decided to establish it in a home of its own. Contributions to this end had been received from all parts of the world, and had made it possible to purchase 26, Portland-place, and to build in its "backyard" the beautiful hall in which the meeting took place. A further sum of £15,000 was, however, needed to meet the obligations in full.



The new hall of Manson House in Portland Place.

The PRINCE OF WALES, in declaring the house open, said that he had always been very interested in tropical medicine. This was not the first function he had performed for the Society, but he felt more fitted to perform it than he had on the last occasion, having since then been stricken with malaria. Some of his more hardened friends in Kenya were not displeased that he had had malaria, since his convalescence was speedy and the reports would be a good advertisement for the colony. Many of our possessions were in tropical regions, and the chief obstacle to our work in them was tropical disease, which was thus of the first importance. Much progress had already been made, largely owing to the effort of great pioneers who had studied tropical diseases on the spot, and had saved hundreds of thousands of lives. The pioneer name that came to their minds that afternoon was of course that of Patrick Manson, after whom the house had been named and whose widow was present. He was in fact the father of modern tropical medicine, and the practical effects of his genius were well illustrated in the completion of the Panama Canal. With the help of that far-seeing statesman, Mr. Joseph Chamberlain, Patrick Manson had founded the School of Tropical Medicine in London, and had been the first President of this Society. Conditions in tropical lands changed rapidly, and one of the most striking changes had been the improvement in communications. These would—unless precautions were taken—tend to increase the spread of disease, but would also advance the ability to control that disease. In this house those who had made discoveries and those who had gained experience would be able to pool their knowledge for the help of future workers.

Sir AUSTEN CHAMBERLAIN proposed a vote of thanks to the Prince for his continuous interest in the study and relief of tropical disease. He very well remembered the extent to which his father had been troubled by the toll of life taken by tropical disease. When the post of medical adviser to the Colonial Office fell vacant Joseph Chamberlain had sought the man in London who knew most about tropical disease, and his inquiries had soon led him to Sir Patrick Manson. Now London had facilities for the study of tropical disease which were unrivalled throughout the world. The death-rate in the tropics at the time Joseph Chamberlain went to the Colonial Office—1896—had been 100 *per* 1000 *per annum;* now it was between 8 and 9 per 1000. No work more beneficent to mankind had ever been done than that of Sir Patrick Manson.

Col. W. P. MACARTHUR, seconding the vote of thanks, mentioned a contribution to Manson House from a cricket club in Rhodesia, the members of which had realised that but for Manson they would not have been playing cricket under conditions almost as healthy as those in England.

The Prince of Wales then went on a tour of the building, an Adam house very pleasantly decorated in green, with oak panelling. On the ground floor is a comfortable members' lounge and a library which will, it is hoped, come to hold on its shelves a complete reference library of tropical medicine. There are also well-fitted cloakrooms, dressing-rooms, and offices. The upper part of the house and the garages are sublet, and provide a useful source of revenue. The well-proportioned hall (illustrated above) is panelled in cream and fitted with rows of brown stalls.

(including those who would *normally* be diagnosed at the later ages of 15 and 16) can be found in this age-group of 14, then we will "discover" 15 cases in 1600 children. As the assumption of finding all sufferers for that year at age 14 could, of course, not hold good, a much smaller number of children with disease would be found, and some of these would be discovered in the ordinary way by the methods and organisations at present at our disposal. Also, and this is very important, two-thirds of the problem —i.e., non-contacts—would remain untouched.

It is interesting to show the possibilities as below, for it also demonstrates the greater risk to contact children.

28,000 girls at school-leaving age.
1,600 contacts. 26,400 non-contacts.
15 T.B. + 30 T.B. +
45 girls T.B. +
15 boys T.B. +
60 T.B. + =
Total cases in one year.

It is, of course, realised that a certain additional number of cases of pulmonary tuberculosis not showing tubercle bacilli would also be disclosed by such an investigation. Nevertheless, the number of sufferers discovered would be small. Investigate as we will we cannot find cases that do not exist.

Such investigation, therefore, hardly appears to be within the scope of the antituberculosis scheme of local authorities. Work of this description, however, should prove a fruitful source of research, as systematic examination of a group of specially susceptible children as indicated could not fail to reveal factors of importance. Children would be found apparently normal at the time of investigation who would develop definite sputum-positive disease subsequently; working backwards, then, to the original findings should, in certain cases, be the means of shedding light on equivocal factors and increasing knowledge about the earliest manifestations of the disease.

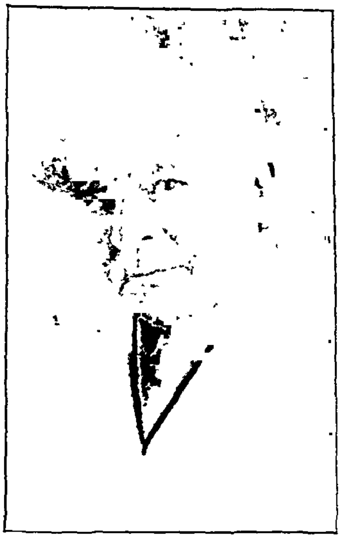
OBITUARY

SIR WILLIAM SMITH, M.D. Aberd., D.Sc. Edin.,

PRINCIPAL OF THE ROYAL INSTITUTE OF PUBLIC HEALTH.

We regret to announce the death of Sir William Smith, principal of the Royal Institute of Public Health, which occurred on March 17th at his house in London in the eighty-third year of his age.



SIR WILLIAM SMITH.

William Robert Smith, the eldest son of Captain T. R. Smith, of the Merchant Service, was born in 1850 in circumstances which compelled him to rely mainly upon his own endeavours for making a career. At the age of 15 he began to earn his own living as an assistant to a chemist, and he so well occupied his spare time as to be able to enter the medical school at St. Bartholomew's Hospital, and later to complete his medical course at Edinburgh, where he obtained the double qualification of the Colleges in 1871. He became house surgeon at the Hants County Hospital, and while there graduated in medicine at Aberdeen, and shortly afterwards received the appointment of medical officer to the old School Board for London, this being a new post. From this time onward he devoted himself with extraordinary energy to the general cause of public health, and to him undoubtedly belongs the credit of having been the first man holding any public position to insist upon the necessity of an educational organisation, to ensure that medical men holding official positions in public health should possess a special diploma. He took an early opportunity of possessing such a diploma himself, securing the D.P.H. Camb. in 1881, about which date he entered as a student at the Middle Temple. On being called to the Bar he obtained an appointment as lecturer in forensic medicine at King's College, London, while he also was chosen as medical officer of health for Woolwich. He found time also to edit the seventh edition of Guy and Ferrier's standard text-book on forensic medicine.

In 1886 he founded the British (now Royal) Institute of Public Health, and for the following 46 years devoted his life to the progress of public health work as represented by the Institute. Seeing that from the beginning such a movement must rely upon public coöperation, he took great interest in municipal politics, was elected mayor of Holborn, and gave valuable service to that great borough out of his personal knowledge of the administration of public health, especially in relation to the welfare of children. In 1894 he presided at the Congress of Public Health in London, in which year he was first elected President of the Institute of Public Health, a position which he held for ten years. In 1910 he was elected vice-chairman of the old Metropolitan Asylums Board, of which he had been a member for a long period, and in 1918 he was Sheriff of London, receiving the honour of knighthood. In that year he stood unsuccessfully as an Independent for the Parliamentary representation of the universities of St. Andrews, Glasgow, and Aberdeen.

From early days Sir William Smith was interested in military matters, and as far back as 1887 was a member of a War Office departmental committee. In 1908, on the creation of the Territorial Force, he became a major, and during the war served as a special sanitary officer with the rank of colonel R.A.M.C.(T.). Into his military duties he threw the same enthusiasm that marked his other official and municipal work, and during all the later phases of his life his energy triumphed over the disabilities of failing health. Holding so many public posts it was inevitable that he should be the recipient of many acknowledgments of his work. He was widely recognised on the continent as an authority on public health, and was the recipient of decorations from the French, Greek, Rumanian, Belgian, and Italian Governments, while he had honorary degrees from the universities of Athens, Geneva, Padua, and Ghent.

One intimately acquainted with both his work and personality writes of Sir William Smith as follows: "William Smith set himself to create (in effect) the national statutory and official basis, facilities and organisation for the system of public health diplomas, training, and appointments which we know to-day. He succeeded. Instant upon that hard-won success there flashed upon the mind of the creative artist a vision of the immeasurable future, national and international, for preventive medicine and public health progress. And, with that vision, William Smith must clearly have seen himself as, of necessity, one of the world leaders in that progress. For England led the world in the domestic sciences. In 1886 he founded the Institute of Public Health. And through the 46 years that followed founder and Institute were one and indivisible. It is no more than the simple truth to assert that, during those years of social revolution, there has been no single episode of progress in public health work that the Institute did not itself initiate or did not actively further and support. Even the creation of the Ministry of Health was mainly due to the persistent efforts of William Smith. Of the perseverance, the mental and physical vigour, the dominating personality, the knowledge of men and matters, these and other factors that made the result possible no casual record can tell. From first to last he was a great fighter. His ideas were new, and the English fear and, therefore, hate novelty. And it was actually within the past two years that, with his advanced age, he accomplished perhaps his most remarkable achievement. Faced with the compulsory demolition of the Institute premises he found, secured, and paid for a near-by plot of freehold land, and only just failed to witness the imminent opening of the new building."

Sir William Smith was twice married. His son by the first marriage is Mr. Corbett-Smith, the well-known publicist and musician. In 1913 he married for the second time Miss Frances Wheeler, J.P., Lady of Grace of the Order of St. John of Jerusalem.

MILK GRADES.

The Milk Ordinance defines eight grades of milk, which are briefly indicated below :—

Certified milk must conform with the current requirements of the American Association of Medical Milk Commissions, and is produced under the supervision of the Medical Milk Commission of the County Medical Society, and of the State Board of Health, or of the City and County Health Officer. It is raw milk produced under stringent sanitary conditions, is sold at a high price, and forms but a very small proportion of the total milk-supply.

Grade "A" raw milk must have an average bacterial count not exceeding 50,000 per c.cm. It must be drawn from cows that have passed a veterinary examination, with tuberculin testing, be cooled within one hour after milking to 50° F. or less, and kept at that temperature until delivery, and be supplied in bottles. It must also be produced under certain hygienic conditions, which are defined in detail.

Grade "B" raw milk must have an average bacterial count not exceeding 200,000 per c.cm. ; otherwise it must conform with all the conditions that are required for grade "A" raw milk, except that the cooling temperature standard is 70° F.

Grade "C" raw milk may have an average bacterial count not exceeding 1,000,000 per c.cm. ; otherwise it must conform with the standards that apply to grade "B" raw milk.

Grade "D" raw milk must, like all milk, contain not less than 3¼ per cent. of milk fat, and 8½ per cent. of solids not fat, but otherwise it is not standardised and must be labelled "cooking only."

Grade "A" pasteurised milk is grade "A" or grade "B" raw milk that has been pasteurised, cooled, and bottled in a milk plant complying with certain hygienic conditions. Its bacterial count must not at any time between pasteurisation and delivery exceed 50,000 per c.cm.

Grade "B" pasteurised milk is grade "C" raw milk pasteurised under all the conditions that apply to grade "A" pasteurised milk.

Grade "C" pasteurised milk is pasteurised milk that does not conform with the requirements of grade "B" pasteurised milk, and it must be labelled "cooking only."

Although the Milk Ordinance provides for no less than eight grades of milk, in practice a smaller number is generally adopted. In many American cities no raw milk, except certified milk, is allowed to be supplied, and by the adoption of compulsory pasteurisation the number of grades has been reduced to three: certified milk, grade "A" pasteurised, and grade "B" pasteurised.

COMPULSORY PASTEURISATION.

The movement for compulsory pasteurisation has made great progress in America in recent years, and is still gaining ground. The movement owes much of its success to the late Mr. Nathan Straus, the well-known philanthropist, who fortunately lived to see the wide acceptance of his views on milk hygiene. Mr. Straus nearly 40 years ago established milk depôts in New York for the supply of pasteurised milk, modified for infant feeding, and was untiring in his advocacy of the compulsory pasteurisation of the general milk-supply. Pasteurisation is now compulsory in New York and many other cities in the United States.

Pasteurisation is defined in the Milk Ordinance as "the process of heating every particle of milk or milk products to a temperature of not less than 142° F., and holding at such temperature for not less than 30 minutes in a pasteurisation apparatus approved by the health officer." In practice it is necessary to make allowance for a margin of error in the thermometers used for recording the temperature of the milk in the container, and also for a deviation between the hottest and coldest particles of milk in the container during the process. A combined "tolerance" of 1½° F. is permitted, so that the recorded temperature required for pasteurisation is 143½° F. It is recommended that approval should not be given to any pasteurising plant with a combined tolerance exceeding 1½° F.

PUBLICITY FOR PASTEURISATION.

The 1931 edition of the Milk Ordinance is preceded by an account of the "Public Health Service Milk Sanitation Program," by Mr. Leslie C. Frank, the sanitary engineer in charge of the Federal *Office of Milk Investigation.* This document contains much practical guidance, based on extensive experience, for city authorities contemplating the adoption of the Ordinance. Compulsory pasteurisation is strongly recommended, and health officers are given suggestions for overcoming possible objections from the public to pasteurisation, one of which is that the process imparts an unpleasant flavour to the milk. To meet this objection, a "*guessing contest*" is suggested :—

> "For example, one of the local pasteurisation plants may furnish both raw and pasteurised milk in quart bottles to the Rotary and other civic luncheons, the bottles being marked with distinguishing marks unknown to the drinkers. Each member should be provided with six glasses, placed in a row in front of him. A small portion of pasteurised milk should be placed in three of the glasses and a small portion of raw milk in the other three in an order unknown to *anyone but the health officer.* The members should not be told how many glasses contain pasteurised milk. Then each member should be asked to tell by tasting which of the six glasses contain pasteurised milk. (It is fundamentally important that the raw milk and pasteurised milk be identically the same milk, except for the fact of pasteurisation. This condition is accomplished best by obtaining the raw milk directly from the pasteuriser just prior to the pasteurisation process, after thorough mixing, and then obtaining the pasteurised milk from the same batch of milk.)
>
> "Each guest should be provided with a small card. The glasses should be considered as being numbered from left to right, and each guest should be asked to write on the card the numbers representing the glasses containing pasteurised milk. Then someone from the speaker's table should announce the true content of each of the six glasses, and all the members who guess correctly may be awarded a prize of some sort."

After such a guessing contest has been tried upon at least 100 persons in the city, the results may, it is suggested, be published in the newspapers as evidence of the fact that proper pasteurisation does not affect the flavour of milk.

DEALING WITH DEFAULTERS.

The Milk Ordinance provides two methods for dealing with defaulting dairymen otherwise than by means of court prosecutions for failure to observe the standards of milk hygiene prescribed: one is the withdrawal of the permit, the other de-grading the milk of the defaulter. By the first method the permit may be withdrawn and the offender prosecuted if he continues to sell his milk without a permit. But this method is, in practice, applicable only in cases of serious default, for otherwise the courts are reluctant to convict, or at all events to impose an adequate penalty. A much more effective method is to de-grade the defaulter's milk and require him to affix a lower grade label to his containers. If he then persists in selling his milk under the higher grade label he can be prosecuted for false labelling, an offence which American courts view with great disfavour. In practice it is seldom necessary to prosecute in such a case, for the offender knows that he will receive short shrift when the court are satisfied that he has not been refused permission to sell his milk, but merely required to label it according to grade. He therefore seldom allows the case to go into court, but promptly complies with the requirements and gets back into his grade as soon as he can.

Advisory Committee) that was not in itself a sufficient reason for not prescribing it if, in his judgment, it was the proper form of treatment, other drugs not being equally efficient. This statement was issued "for the practitioner's future guidance," no ground for complaint being found against him. The panel committee regarded it as a "homily," and protested to the medical members of the insurance committee on the form of the wording which, whatever the strict legal position, seemed to take away from the doctor a useful argument for not prescribing a preparation when demanded by a patient who has great faith in it.

National Formulary.

There are in the National Formulary certain preparations of which the directions for use are printed with the formulæ; in the absence of any direction on the prescription, the chemist has to label the preparation according to this standard direction. If the practitioner writes directions himself, those directions take precedence over those of the standard formulary. But if he simply gives verbal instruction to the patient as to how the medicine should be used, the chemist puts on the bottle the formulary directions which may be different. Trouble is then likely to arise between doctor, chemist, and patient. The London Panel Committee, on the advice of its pharmacy subcommittee and after full discussion, decided to ask the Insurance Acts Committee to negotiate with the Ministry for the deletion from the Formulary of the printed directions.

Choice of Doctor.

The ethical subcommittee of the London Panel Committee has succeeded in persuading a hotel not to force its employees to go on the hotel doctor's panel. The hotel had issued a leaflet to its staff in he following terms:—

> Insured persons have the right of selecting their own anel doctor.
>
> It is, however, a great convenience to employees and to he company for employees to be on the hotel doctor's anel.
>
> Are you willing to transfer to this panel?
> (Write "Yes" or "No")........
> Signature......................

In reply to a request from the panel committee to leal with the matter, the Ministry stated they were not aware of any action that could usefully be taken. Eventually, however, the hotel representative asked what wording the panel committee would suggest, and the following was approved:—

> Insured persons have the right of selecting their own panel doctor. You are requested to make your selection from the doctors in the immediate neighbourhood at once.

Thus the free choice of doctor was maintained in this neighbourhood.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

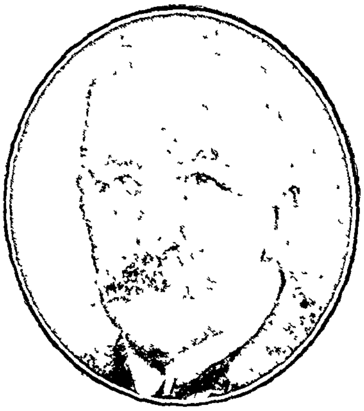
A CROSS SECTION OF A DIABETIC HOSPITAL SERVICE.

WHAT is probably a fairly characteristic sample of diabetic careers under modern hospital conditions was given by Prof. Marcel Labbé in a communication to the Academy of Medicine on Feb. 9th. His cross section dealt with the year 1930, when 136 diabetics were treated in the wards of the Pitié, and 314 in its out-patient department. The in-patients for the most part represented a more serious phase of the disease than did the out-patients; a feature of the resident treatment was education of the patient in the technique of his own treatment. Patients who refused admission to hospital were coached by a social service worker in the graduation of their diets and the daily examination of their urines for glycosuria by Gerhardt's test. They were also taught the technique of insulin injections, and given printed instructions on how to avoid diabetic coma. Contact was maintained between these patients and the hospital through their visits once or twice a month to call for their insulin. The social worker who visited patients in their homes found them occasionally on the verge of coma, and brought them back to hospital and to life. In spite of surveillance and education, many patients died simply because they did not take the necessary trouble to live, and every summer holiday, away from home and supervision, yielded a crop of disasters. Among the 136 in-patients during the year there were 17 deaths, and among the 314 out-patients 20 deaths. Pulmonary tuberculosis was responsible for 24 per cent. of the deaths; diabetic coma and Bright's disease each for 13·5 per cent.; and infections and septicæmia for 10·8 per cent. The mortality from tuberculosis might be reduced by keeping the diabetic in a separate ward to which the tuberculous are never admitted, and by artificial pneumothorax treatment which, in Prof. Labbé's opinion, provides the diabetic's *only* chance of recovery. It says much for the modern treatment of diabetes that, while in Prof. Labbé's material only 13·5 per cent. of the deaths were due to diabetic coma, this condition was responsible for 60 per cent. of the deaths of diabetics in Naunyn's time.

PERI-ARTICULAR INJECTIONS OF NOVOCAIN IN TRAUMATIC ARTHRITIS.

Some interest has been aroused by the account given in the *Presse Médicale* for Feb. 20th, by Dr. R. Leriche and Dr. R. Fontaine, of Strasbourg, of the way in which a simple diagnostic device developed into what they now consider a valuable therapeutic measure. In March, 1930, one of them was engaged on a study of the sensory nerve-supply of the joints. He found that by the injection of an anæsthetic into the ligaments and insertions of tendons about joints, it was possible to dissociate purely mechanical ailments thereof from accompanying functional disturbances. Sometimes he was able to demonstrate the existence of functional disturbances which were alone responsible for symptoms and impaired movement about a joint. While engaged on the differential diagnosis of complaints of the joints, the authors observed an unexpected therapeutic effect of their injections. In every case in which the mechanical element was trifling, and reflex disturbances dominated the clinical picture, the functional improvement following these injections lasted much longer than the actual local anæsthesia; and when these symptoms occurred, they were, as a rule, much less pronounced than before. This led to the repetition of the injections four or five times, and to the complete disappearance of all the symptoms in certain cases of sprains and traumatic arthritis. Left to themselves, such cases sometimes clear up after a long period of stiffness, but functional defects often persist. Occasionally these cases end in veritable chronic arthritis deformans although, at the outset, according to the author, a complete cure could easily have been effected by peri-articular injections of an anæsthetic, a measure within the sphere of activity of every practitioner. They believe peri-articular infiltration is more satisfactory than intra-articular injection, and that

GEORGE BROWN HILLMAN, M.B.E., L.M.S.S.A., J.P.



DR. HILLMAN.

WE regret to announce the death on March 19th of Dr. G. B. Hillman, Member of Parliament for Wakefield. He had been lying ill for some days in London with bronchitis, when death took place suddenly from heart failure. George Brown Hillman was a son of the late Rev. S. D. Hillman, of Ilkley. He was educated at Ilkley High School, going on to the Leeds School of Medicine, where he took the Hardwick prize in clinical medicine and qualified L.S.A. in 1892. Soon after qualification he held resident appointments at the Leeds Hospital for Women and Children; he then started in general practice in the Castleford district of the West Riding, with sanitary charge of that and the Whitwood urban district, and became a steadily growing influence in local medical politics. In 1915 he received a commission in the R.A.M.C., reaching the rank of major in the Malta Command, where he was in charge first of the Spinola General Hospital and later of the Hamrun Military Hospital. On returning to Wakefield he soon became chairman of the West Riding local medical and panel committee, and was increasingly occupied in public work, becoming a member of the city council in 1926 and mayor of Wakefield in 1928. For a time he was chairman of the medical propaganda subcommittee of the British Empire Cancer Campaign. He first stood for Parliament at the general election of 1923, when he contested unsuccessfully the Normanton division. At the election in October last, standing for Wakefield as Conservative, he won the seat from Mr. G. H. Sherwood, another ex-mayor of the town. In 1895 Dr. Hillman married Christina, daughter of Mr. John Henderson, of Bradford.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 12TH, 1932.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 76 (last week 41); scarlet fever, 1610; diphtheria, 818; enteric fever, 23; pneumonia,* 1929; puerperal fever, 42; puerperal pyrexia, 119; cerebro-spinal fever, 72; acute poliomyelitis, 1; polio-encephalitis, 1; encephalitis lethargica, 11; dysentery, 17; ophthalmia neonatorum, 112. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on March 15th–16th was as follows: Small-pox 110 under treatme

week 101 and 7 respectively);

1551; enteric fever, 10; measles, 2048; whooping-cough, 400; puerperal fever, 23 (plus 9 babies); encephalitis lethargica, 226; poliomyelitis, 4; "other diseases," 196. At St. Margaret's Hospital there were 13 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 3 (0) from enteric fever, 81 (36) from measles, 8 (2) from scarlet fever, 46 (7) from whooping-cough, 24 (2) from diphtheria, 46 (14) from diarrhœa under two years, and 292 (59) from influenza. The figures *in parentheses* are those for London itself.

The deaths from influenza are dropping slowly. Of the great towns Birmingham stands highest with 21 deaths, followed by Bristol with 15 and Norwich with 11. The total deaths for the year from influenza so *far amount* to 3220, compared with 3504 for the corresponding period of 1931. The deaths from typhoid and *paratyphoid* fevers occurred in Eastbourne, Birkenhead, and Newcastle-*on*-Tyne. West Ham reported 6 deaths from measles, Ealing, Manchester, and Stoke-on-Trent each 4. *Whooping-cough* accounted for 6 deaths at Birmingham, 4 at Manchester. Diphtheria was credited with 4 deaths at Hull, 3 at Wakefield.

The number of stillbirths notified during the week was 312 (corresponding to a rate of 47 per 1000 births), including 47 in London.

---

* Now more accurately defined in the summary as Acute pneumonia (primary or influenzal).

PANEL AND CONTRACT PRACTICE

A Question of Prescribing.

THE London Panel Committee at its last meeting took exception to the report issued by the medical service subcommittee of the London Insurance Committee on a case relating to the prescribing of patent remedies. A man had contracted asthma on war service and was advised by the Ministry of Pensions to take a certain rather expensive proprietary preparation for the alleviation of this distressing condition. He purchased this for some time and then asked the Ministry to allow him some grant towards the expense, using the argument that if the Ministry can pay for the supply and repair of artificial limbs, necessitated by war injuries, why should they not help him to pay the cost of treating his own war injury—viz., asthma. This, however, could not be done, but he was told he could get the preparation through the panel. He thereupon consulted his panel doctor, without however actually asking him to prescribe the preparation on an insurance form. The doctor, it appears, would not have prescribed it because the formula had not been disclosed, and there was no special condition which would have justified him prescribing it when other and equally efficient remedies were available. These other remedies were in fact prescribed, and the patient admitted they had done him much good. He continued, however, with the doctor's knowledge, to obtain the proprietary article, and eventually appealed to the insurance committee for a refund of the cost. When the case came before the medical service subcommittee the doctor mentioned that one reason for *not prescribing* the article was its inclusion in the schedule of drugs or medicines drawn up by the Drugs Advisory Committee, the composition of which had not been disclosed. The Advisory Committee having expressed the view that the prescribing of such a drug could only be justified in exceptional cases, *and that* the justification would be difficult to substantiate, he thought he could not prescribe it without being surcharged. The subcommittee advised him that the responsibility was his own to decide, in any particular case, what was proper and sufficient medicine; and because a preparation was in a *certain list* (even drawn up by so responsible a body as the Drug

Advisory Committee) that was not in itself a sufficient reason for not prescribing it if, in his judgment, it was the proper form of treatment, other drugs not being equally efficient. This statement was issued "for the practitioner's future guidance," no ground for complaint being found against him. The panel committee regarded it as a "homily," and protested to the medical members of the insurance committee on the form of the wording which, whatever the strict legal position, seemed to take away from the doctor a useful argument for not prescribing a preparation when demanded by a patient who has great faith in it.

National Formulary.

There are in the National Formulary certain preparations of which the directions for use are printed with the formulæ; in the absence of any direction on the prescription, the chemist has to label the preparation according to this standard direction. PANEL AND CONTRACT PRACTICE

A Question of Prescribing.

The London Panel Committee at its last meeting took exception to the report issued by the medical service subcommittee of the London Insurance Committee on a case relating to the prescribing of patent remedies. A man had contracted asthma on war service and was advised by the Ministry of Pensions to take a certain rather expensive proprietary preparation for the alleviation of this distressing condition. He purchased this for some time and then asked the Ministry to allow him some grant towards the expense, using the argument that if the Ministry can pay for the supply and repair of artificial limbs, necessitated by war injuries, why should they not help him to pay the cost of treating his own war injury—viz., asthma. This, however, could not be done, but he was told he could get the preparation through the panel. He thereupon consulted his panel doctor, without however actually asking him to prescribe the preparation on an insurance form. The doctor, it appears, would not have prescribed it because the formula had not been disclosed, and there was no special condition which would have justified him prescribing it when other and equally efficient remedies were available. These other remedies were in fact prescribed, and the patient admitted they had done him much good. He continued, however, with the doctor's knowledge, to obtain the proprietary article, and eventually appealed to the insurance committee for a refund of the cost. When the case came before the medical service subcommittee the doctor mentioned that one reason for not prescribing the article was its inclusion in the schedule of drugs or medicines drawn up by the Drugs Advisory Committee, the composition of which had not been disclosed. The Advisory Committee having expressed the view that the prescribing of such a drug could only be justified in exceptional cases, and that the justification would be difficult to substantiate, he thought he could not prescribe it without being surcharged. The subcommittee advised him that the responsibility was his own to decide, in any particular case, what was proper and sufficient medicine; and because a preparation was in a certain list (even drawn up by so responsible a body as the Drug

Advisory Committee) that was not in itself a sufficient reason for not prescribing it if, in his judgment, it was the proper form of treatment, other drugs not being equally efficient. This statement was issued "for the practitioner's future guidance," no ground for complaint being found against him. The panel committee regarded it as a "homily," and protested to the medical members of the insurance committee on the form of the wording which, whatever the strict legal position, seemed to take away from the doctor a useful argument for not prescribing a preparation when demanded by a patient who has great faith in it.

National Formulary.

There are in the National Formulary certain preparations of which the directions for use are printed with the formulæ; in the absence of any direction on the prescription, the chemist has to label he preparation according to this standard direction. If the practitioner writes directions himself, those directions take precedence over those of the standard formulary. But if he simply gives verbal instruction o the patient as to how the medicine should be used, the chemist puts on the bottle the formulary directions which may be different. Trouble is then ikely to arise between doctor, chemist, and patient. The London Panel Committee, on the advice of its pharmacy subcommittee and after full discussion, decided to ask the Insurance Acts Committee to negotiate with the Ministry for the deletion from the Formulary of the printed directions.

Choice of Doctor.

The ethical subcommittee of the London Panel Committee has succeeded in persuading a hotel not to force its employees to go on the hotel doctor's panel. The hotel had issued a leaflet to its staff in the following terms:—

> Insured persons have the right of selecting their own panel doctor.
>
> It is, however, a great convenience to employees and to the company for employees to be on the hotel doctor's panel.
>
> Are you willing to transfer to this panel?
> (Write "Yes" or "No")........
> Signature ....

In reply to a request from the panel committee to deal with the matter, the Ministry stated they were not aware of any action that could usefully be taken. Eventually, however, the hotel representative asked what wording the panel committee would suggest, and the following was approved:—

> Insured persons have the right of selecting their own panel doctor. You are requested to make your selection from the doctors in the immediate neighbourhood at once.

Thus the free choice of doctor was maintained in this neighbourhood.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

A CROSS SECTION OF A DIABETIC HOSPITAL SERVICE.

WHAT is probably a fairly characteristic sample of diabetic careers under modern hospital conditions was given by Prof. Marcel Labbé in a communication to the Academy of Medicine on Feb. 9th. His cross section dealt with the year 1930, when 136 diabetics were treated in the wards of the Pitié, and 314 in its out-patient department. The in-patients for the most part represented a more serious phase of the disease than did the out-patients; a feature of the resident treatment was education of the patient in the technique of his own treatment. Patients who refused admission to hospital were coached by a social service worker in the graduation of their diets and the daily examination of their urines for glycosuria by Gerhardt's test. They were also taught the technique of insulin injections, and given printed instructions on how to avoid diabetic coma. Contact was maintained between these patients and the hospital through their visits once or twice a month to call for their insulin. The social worker who visited patients in their homes found them occasionally on the verge of coma, and brought them back to hospital and to life. In spite of surveillance and education, many patients died simply because they did not take the necessary trouble to live, and every summer holiday, away from home and supervision, yielded a crop of disasters. Among the 136 in-patients during the year there were 17 deaths, and among the 314 out-patients 20 deaths. Pulmonary tuberculosis was responsible for 24 per cent. of the deaths; diabetic coma and Bright's disease each for 13·5 per cent.; and infections and septicæmia for 10·8 per cent. The mortality from tuberculosis might be reduced by keeping the diabetic in a separate ward to which the tuberculous are never admitted, and by artificial pneumothorax treatment which, in Prof. Labbé's opinion, provides the diabetic's only chance of recovery. It says much for the modern treatment of diabetes that, while in Prof. Labbé's material only 13·5 per cent. of the deaths were due to diabetic coma, this condition was responsible for 60 per cent. of the deaths of diabetics in Naunyn's time.

PERI-ARTICULAR INJECTIONS OF NOVOCAIN IN TRAUMATIC ARTHRITIS.

Some interest has been aroused by the account given in the *Presse Médicale* for Feb. 20th, by Dr. R. Leriche and Dr. R. Fontaine, of Strasbourg, of the way in which a simple diagnostic device developed into what they now consider a valuable therapeutic measure. In March, 1930, one of them was engaged on a study of the sensory nerve-supply of the joints. He found that by the injection of an anæsthetic into the ligaments and insertions of tendons about joints, it was possible to dissociate purely mechanical ailments thereof from accompanying functional disturbances. Sometimes he was able to demonstrate the existence of functional disturbances which were alone responsible for symptoms and impaired movement about a joint. While engaged on the differential diagnosis of complaints of the joints, the authors observed an unexpected therapeutic effect of their injections. In every case in which the mechanical element was trifling, and reflex disturbances dominated the clinical picture, the functional improvement following these injections lasted much longer than the actual local anæsthesia; and when these symptoms occurred, they were, as a rule, much less pronounced than before. This led to the repetition of the injections four or five times, and to the complete disappearance of all the symptoms in certain cases of sprains and traumatic arthritis. Left to themselves, such cases sometimes clear up after a long period of stiffness, but functional defects often persist. Occasionally these cases end in veritable chronic arthritis deformans although, at the outset, according to the author, a complete cure could easily have been effected by peri-articular injections of an anæsthetic, a measure within the sphere of activity of every practitioner. They believe peri-articular infiltration is more satisfactory than intra-articular injection, and that

purely of a supervisory character.—Sir BOLTON EYRES-MONSELL replied: There are no dental officers of the rank of surgeon-captain employed in the Navy at a remuneration of £3 9s. a day. One surgeon-captain (D) only is allowed in the establishment of dental officers, this officer being employed at the Admiralty on the staff of the Medical Director-General of the Navy, to whom he is responsible for the entire administration of the naval dental service. His duties necessarily include those of a supervisory character. His pay is at the current rate of £3 a day, plus the usual allowances.

THURSDAY, MARCH 17TH.

Women Workers in Factories.

Mr. THOMAS WILLIAMS asked the Home Secretary the number of women workers in the factories of England and Wales; the number of factories that might be inspected by his department; and the number of women inspectors available for inspection duties.—Sir HERBERT SAMUEL replied: Returns show that in 1930 there were 1,806,850 women and girls employed in factories: the figure for 1931 is not yet available. The number of registered factories *at the end of 1931 was 155,354.* There are at present 56 women inspectors in the divisional and district staffs. It would, of course, not be practicable to lay down any rule that factories where women only are employed should be inspected only by women inspectors.

Attacks on Women and Girls.

Mr. LEWIS asked the Home Secretary whether since the introduction of women police the number of cases of attacks on women and girls had a tendency to increase or to decrease.—Sir H. SAMUEL replied: Since women police were first employed, during the war, the reported numbers of some kinds of attacks on women and girls have decreased, *while others have increased. Such fluctuations are due to* various factors, and I am unable to suggest any direct relation between them and the employment of women police.

Medical Staff of the Ministry of Health.

Mr. J. A. L. DUNCAN asked the Minister of Health the number of salaried persons holding medical qualifications on the headquarters staffs of the Ministry of Health in March, 1925, and March, 1932.—Mr. ERNEST BROWN (Parliamentary Secretary to the Ministry of Health) replied: The numbers are 56 and 52 respectively.

National Health Insurance.

Mr. RHYS DAVIES *asked the Minister of Health whether* he proposed to introduce legislation to deal with the problems connected with national health insurance; and, if so, when.—Mr. ERNEST BROWN replied: The problems to which the hon. Member refers are receiving my right hon. friend's most careful consideration as a matter of urgency but he is not yet in a position to make any statement as to the introduction of legislation to deal with them.

Captain STRICKLAND asked the Minister of Health the reason for the present disadvantageous position of deposit contributors compared with contributors through an approved society under the National Health Insurance Acts; and whether he would consider an early amendment granting them equal privileges.—Mr. ERNEST BROWN replied: The National Health Insurance scheme has from the first been based on the provision of benefits to insured persons through approved societies, and the full advantages of the scheme can only be obtained through membership of a society. My right hon. friend sees no reason for amending the Act in this respect. The Act already contains special provision to meet the case of insured persons who, by reason of ill-health, are unable to secure admission to an approved society.

Training of Midwives.

Lieut.-Colonel FREMANTLE asked the Minister of Health the total amount of grants disbursed by the Ministry during the year ended April 5th, 1931, towards the training of midwives; whether the grants were paid direct to training schools; and, if so, the number of pupils trained under such grants and the number proposing to practise as midwives and health visitors respectively.—Mr. ERNEST BROWN replied: The total amount of the grants disbursed by the Ministry during the year ended April 5th, 1931, towards the training of midwives was £21,363. These grants were paid direct to the training schools. The number of pupils in respect of whom grants were paid was 752, of whom 717 proposed to practise as midwives, and 35 as health visitors.

Lieut.-Colonel FREMANTLE asked the Minister of Health whether any regulations regarding the payment of grants for the training of midwives had been made under the Local Government Act, 1929.—Mr. ERNEST BROWN replied: No, Sir. The conditions governing the payment of grants for this purpose were settled and published in 1925, and were not affected by the passing of the Local Government Act of 1929.

Preservatives in Foreign Bacon.

Mr. THORNE asked the Minister of Health if he was aware that some bacon imported from America was cured in a solution of borax for preservation in transit; and what steps were taken by his department to ensure that bacon so cured was not harmful to the health of the consumer.—Mr. ERNEST BROWN *replied: The importation of* bacon cured with borax is prohibited under the Preservatives Regulations. My right hon. friend is not aware of any recent contravention of the regulations in this respect, but if the hon. Member will give him any particulars in his possession inquiries will be made.

MONDAY, MARCH 21ST.

Thames Floods Prevention.

Mr. MOREING asked the Minister of Health whether a decision had been arrived at with regard to the resumption of the work of the Departmental Committee on Thames Floods Prevention; whether it was expected that the committee would resume its sittings; and whether he would urge the committee to expedite its deliberations and issue a report at an early date.—Sir E. HILTON YOUNG replied: The question of the resumption of the sittings of this Departmental Committee is under consideration, and I *cannot at the moment add anything to the reply given to* my hon. friend on March 3rd.

Heavy Traffic in Medical Areas.

Sir JAMES REYNOLDS asked the Minister of Transport if he was aware of the annoyance caused by the use for heavy traffic of streets devoted primarily to the medical profession; and if he would consider taking steps to ensure that such streets be kept free of such traffic for the benefit of patients where there were alternative routes conveniently available.—Mr. PYBUS replied: I am afraid it would be impracticable to impose restrictions such as my hon. and gallant friend suggests.

Public Health Services in India.

Dr. MORRIS-JONES asked the Secretary for India whether any decision had been arrived at regarding the proposal to abolish the post of director of public health in the United Provinces and to amalgamate the public health department with the medical department under the inspector-general of civil hospitals.

Lieut.-Col. FREMANTLE asked the Secretary for India whether any decision had been made regarding the proposal to abolish the post of director of public health in the United Provinces and to amalgamate the public health department with the medical department under the inspector-general of civil hospitals; whether he would state the reasons for and against the proposal; and in what way it was proposed to safeguard the health of the people not in hospital.—Sir S. HOARE replied: I have not heard of any such proposal as regards the United Provinces. Perhaps my hon. friends are referring to the Central Provinces where a proposal to combine temporarily the posts of director of public health and the inspector-general of civil hospitals is under consideration as a measure of economy.

Duties of Medical Staff of Ministry of Health.

Sir CHARLES CAYZER asked the Minister of Health whether any of the whole-time members of his medical staff performed duties or held appointments other than such as were connected officially with his department for which they received emoluments not provided by the State.—Sir E. HILTON YOUNG replied: The answer is in the affirmative. I should, however, make it clear that the performance of any such duties or the holding of any such appointments (which consist of the delivering of occasional lectures or acting temporarily as examiners) are only allowable where they do not interfere with the regular duties of the position of an officer as a public servant, or with the public interest.

The Silicosis Scheme.

Mr. NEIL MACLEAN asked the Home Secretary what was the total sum paid out under the Various Industries (Silicosis) Scheme since the inception of the scheme for England and Wales and for Scotland, respectively.—Sir H. SAMUEL replied: I regret that separate figures as to the compensation paid under the Various Industries and Metal Grinding Industries Schemes, which are identical except as regards the processes to which they apply, are not available, but the total compensation paid under these two schemes during 1929 and 1930 was £46,783. I have no information as to the proportion paid in England, Wales, and Scotland respectively. The figures for 1931 are not yet available.

Mr. NEIL MACLEAN asked the Home Secretary if any steps were being taken by the Home Office to have plant installed y the employers to prevent silicosis.—Sir H. SAMUEL eplied: Much has been and is being done in this irection. Regulations to prevent silicosis have been ade under the Factory and Workshop Act, 1901, for number of industries, including the manufacture of ilica bricks, the manufacture of cutlery and edge tools, and e grinding of metals and cleaning of castings, and a upplementary code of regulations for the pottery industry has recently been agreed with the industry, and will be brought into force very shortly. All these regulations include requirements involving the installation of plant to prevent inhalation of dust. Further, it is the general practice of the inspectors under Section 74 of the Act to require the provision of exhaust ventilation in any case where the workers are exposed to this risk. The prevention of silicosis in mines and quarries is a matter for the Mines Department.

MEDICAL NEWS

niversity of Oxford.

Wilbert Hurst Brown, B.M., has been elected to the adcliffe travelling fellowship for 1932.

niversity of London.

At a meeting of the Senate, held on March 16th, Prof. arl Prausnitz was appointed Heath Clark lecturer for the ar 1932; Sir John Rose Bradford, F.R.S., has been elected vice-chairman of the University College Committee r the year 1932–33.

oyal College of Physicians of London.

At a meeting of the College on March 21st Lord Dawson Penn was re-elected President.

Diplomas in ophthalmic medicine and surgery were anted, jointly with the Royal College of Surgeons, to the llowing:—

G. P. Barua, W. M. Box, T. N. D'Arcy, A. A. Al Rahim ahmy, Kamala Ghosh, Andrew Grant, Y. M. Khan, Surendra th Mitter, . M. Moffatt, G. E. Plowright, Alison L. Taylor, d E. H. Walker.

The College will be closed from Friday, March 25th, till uesday, March 29th, both days inclusive.

niversity of Liverpool.

At recent examinations the following candidates were ccessful:—

D.M.R.E.

J. P. Grieve, W. Griffiths, R. B. Guyer, P. T. K. Nayar, . L. Rubin, J. S. Tomb, and Sylvia Wigoder.

D.T.M.

B. N. Bhandari, P. Dass, J. A. Doherty, and R. L. Portway.

D.T.H.

G. P. F. Bowers, A. Cathcart, T. K. Kurivila, I. C. Middleton, d H. J. H. Spreadbury.

D.P.H.

Part I.—F. J. H. Crawford, Rita Henry, E. D. Irvine, . W. Paton, M. Solomon, and Honora J. Twomey.

niversity of Dublin.

At recent examinations in the School of Physic, Trinity ollege, the following candidates were successful:—

FINAL EXAMINATION FOR M.B., B.CH., AND B.A.O.

Part I.—Materia Medica and Therapeutics; Medical Juris-rudence and Hygiene; Pathology and Bacteriology: *D. M. itchell, *R. B. Hunter, Mary E. Mansfield, George Hannigan, . J. Roberts, J. S. Ruddell, Marion A. G. Kennedy, G. S. S. arty, R. G. B. Wigoder, E. S. A. Ashe, W. P. Griffin, and . N. Taylor.

Part II.—Medicine: D. C. Evans, J. G. Wilson, H. J. arland, H. B. Wright, and M. A. Shapiro. *Surgery:* D. B. radshaw, H. S. Mason, L. L. Nel, A. J. O'Connor, H. J. Garland, athleen R. Byrne, T. J. O'Sullivan, Joseph Elliman, P. H. eacock, E. S. Samuels, M. A. Shapiro, and Edward Morrison. *idwifery:* *J. N. Concannon, *S. N. Varian, H. B. Wright, J. A. Mallie, W. M. E. Anderson, D. T. Annesley, W. T. Bermingham, and Elizabeth G. Graham.

* Passed on high marks.

Instruction for D.P.H.

A three-months' course of lectures and demonstrations on Clinical Practice and in Hospital Administration will be given at the Brook Hospital, Shooter's Hill, Woolwich, London, S.E.18, by Dr. J. B. Byles, the medical superintendent, on Tuesdays and Fridays at 3 P.M., and alternate Saturdays at 11 A.M. from Tuesday, April 5th. Further particulars may be had from the Medical Officer of Health, London County Council, Public Health Department (Special Hospitals), Victoria Embankment, E.C.4.

Royal Sanitary Institute.

A sessional meeting will be held at York, in conjunction with the Yorkshire branch of the Society of Medical Officers of Health and the North-Eastern Centre of the Sanitary Inspectors Association, on April 1st and 2nd, 1932, when papers will be read on Medical and Social Conditions in Soviet Russia, by Dr. W. W. A. Kelly; on York's Experience with Tuberculous Milk, by Mr. Frank Fishburn; and on Non-pulmonary Tuberculosis in York, by Dr. P. R. McNaught.

Post-graduate Work at Dundee.

A course of lectures will be given at Dundee Royal Infirmary at 3.15 P.M. on Thursdays from April 7th to May 26th. The first, on Gastric and Duodenal Ulceration, will be given by Dr. W. E. Foggie and Mr. John Anderson.

London Hospital Medical College.

The subject chosen for the Hutchinson triennial prize dissertation for 1935 is Septic Infections of the Hand, with special regard to the End Result. Particulars will be found in our advertisement columns.

Elizabeth Garrett Anderson Hospital

Last year there were 2893 in-patients, an increase of 95, and 7492 out-patients. Although there was a deficit of £1564, the income increased by £1166 and the expenditure fell by £514.

Higgins Memorial Sterilising Room at Louth.

As a memorial to the late Dr. W. R. Higgins, a new sterilising room has been provided in the Louth District Hospital. Dr. Higgins, who died on August 22nd, 1930, was for 24 years honorary medical officer of the institution and a very popular surgeon in the town. The sterilising room, which cost about £250, has been provided by public subscription, and the equipment in it is the gift of the management committee of the hospital. The opening ceremony was performed by Major E. F. Finch, F.R.C.S., who said that in providing this addition to the hospital they were fulfilling one of the greatest desires of Dr. Higgins's heart. A vote of thanks to Major Finch was proposed by Dr. Laughton Smith and seconded by Colonel L. P. Stephen, honorary surgeon to the hospital.

Medical Superintendents' Society.

The annual dinner of the Society was held on March 19th at the Langham Hotel, London. Some 75 members and guests were present, the President of the Society, Dr. J. Basil Cook, being in the chair. The health of the Society was proposed by Dr. H. L. Eason, and responded to by Dr. Cook, who outlined the part the Society had taken during the past 45 years in the evolution of the municipal hospitals, and urged the importance of making their vast storehouses of clinical material available for medical students. The health of the visitors was proposed by Dr. Clifford Ellingworth and responded to by Dr. F. R. Seymour. Amongst the guests were Prof. W. W. Jameson, Dr. J. Tate, Dr. Allen Daley, Dr. Letitia Fairfield, Dr. James Neal, and Dr. J. W. Bell.

Irish Medical Schools and Graduates Association.

The St. Patrick's Day dinner of the Association was held on March 17th at the Piccadilly Hotel, London, Dr. Howard Humphris presiding over a gathering of the members and their friends. The feature of the evening was the presentation of the Arnott Memorial Medal of the Association to Sir William Taylor, the well-known Dublin surgeon, who is understood to have been largely responsible for the movement popularly known as the "Irish Sweeps," by which the hospitals of his country have so largely benefited. Mr. J. F. Peart delivered an eloquent justification of the selection of Sir William Taylor as recipient of the medal, touching briefly upon the "Sweeps," while pointing out that the Association was honouring one who had been president of the Royal College of Surgeons in Ireland, was consulting surgeon to several large Dublin Hospitals, and a pioneer in gastric surgery. Sir William Taylor, in a brief reply, pointed out that the distribution of the prizes had brought happiness to a great many, while there could be no doubt of the enormous importance to the medical charities of the large sums of money obtained. The toast of "the Guests" was also left in the hands of Mr. Peart, who coupled with it the name of the Envoy Extraordinary and Minister Plenipotentiary for Egypt. His Excellency briefly replied, when the toast of prosperity to the Association was proposed by Mr. Patrick J. H. Hannon, M.P., and replied to by Dr. Humphris. A short musical programme was provided, which consisted in the singing of appropriate songs by Miss Wynne Ajello and Mr. Dennis O'Neil.

but important thesis, should direct our attention to the rôle of diet in the production of urinary calculi.

Bed-wetting by children in institutions can be eliminated by limiting fluid intake immediately before bedtime, and giving extra blankets in cold weather. It can be enhanced by allowing the children to sleep on a cold mackintosh covered by a single sheet. the cruel routine of most hospitals in the country to-day.

THE RÔLE OF INFECTIONS.

Infections of all kinds play their part in the beginning of urinary disease, and a free fluid intake of milk, water, and salines should therefore be tried, with alkalis, by all who treat febrile conditions.

Less appreciated is the part played by drastic purgation. Recently a patient was sent to hospital as a case of acute appendicitis, and on inquiry she confessed to taking half a bottle of cascara and several other purgatives. Intestinal colic had followed, with a bacilluria so brisk that the kidneys bled profusely. Under alkalis and rest the appendicitis did not mature, though many an attack of appendicitis has been caused by the homely over-dosage of a purgative. Transient albuminuria, bacilluria, and hæmaturia are so often present in appendicitis that there is sometimes danger of delay in removing this dangerous organ. The chances of operating upon a normal appendix and leaving a gangrenous kidney are so remote that the description of such an accident might well be left to urological journals.

In all cases of frequency with temperature and the associated symptoms the diagnosis may be one of pyelitis, but it is our duty to ascertain whether the infection is primarily renal and hæmatogenous—a descending infection—or whether the infection is reaching the kidneys along the lumen of the ureter from the bladder: the ascending pyelonephritis or surgical kidney of former days. The hæmatogenous origin of renal infections has been over-written, but more and more evidence is accumulating in favour of equal acceptance of the ascending and descending origins. Cunningham and Graves[1] have demonstrated the ease with which regurgitation occurs from the bladder to the kidney in the anæsthetised animal, and quote Kretschmer, who in 1916 found regurgitation in three out of ten children under ether anæsthesia and considered straining a factor. To-day we find the radiologists pressing on the bladder in order to obtain a better renal picture in intravenous pyelography—so much for the efficacy of the lower end of the ureter as a sphincter! If the unilateral nature of pyelitis has been exaggerated, so also has the bilateral nature of ascending infections. Unilateral pyelitis may be secondary to cystitis—most often on the right side.

> A man, catheterised three days previously for vesical congestion, suddenly developed pain and a swelling in the right loin so large that I thought an operation necessary, but Mr. Thomas in consultation wisely remarked: "The kidney is not an appendix; it will stand a lot of tension. Wait a few days and see what happens." I did, and after about a week the swelling subsided, never to recur during the remaining four years of the patient's life.

In primary renal cases, often with recognisable foci of infection, alkalis produce dramatic cures. Carbonate of soda is again displacing citrates, which are often nauseating in large quantities but are more palatable when prescribed as an effervescing tablet. Their administration should be continued for 14 days, after which sodium acid phosphate is indicated. Or, of course, the latest urinary antiseptic may be given, a careful watch being kept for any recurrence of scalding or frequency. Mercurial compounds should be avoided.

VALUE OF INSTRUMENTATION.

Many cases become chronic and run alarming temperatures for five weeks or more. The patient, desperately ill and wasted to a shadow, is tested for typhoid and tuberculosis with negative results. Vaccines are prepared and a result is sometimes obtained, usually about the time the patient would normally be improving if left alone. We have all experienced these desperate cases. Some have yielded to catheter drainage, others are cured the moment they are cystoscoped, and so I was led to search my records for a cause of these unexpected and dramatic cures. My first experience really started my interest in dysuria.

> In 1911 a woman presented herself with pain and frequency of months' standing, and by means of cystoscopy a solitary ulcer of the bladder (Hunner's ulcer) was diagnosed by Mr. R. A. Bickersteth. I was instructed to wash out the bladder next day with silver nitrate. I did this once, but caused so much pain that I had to desist. Next day she said she was better, and I left well alone. Two years later I heard that she was quite well and had had no recurrence of symptoms. How one irrigation of silver nitrate could cure an ulcer puzzled me; it has never done so outside urinary surgery.

Another case was one sent by Dr. Henry Cohen:—

> The patient complained of long and tiresome dysuria; alkalis and vaccines had been useless, and a previous cystoscopy had been done. I reported the usual blurred mucosa, adherent flakes of pus, and œdematous ureteric orifices, with apologies for paucity of treatment. Imagine my surprise when the patient reported improvement a month later! The only difference in the treatment had been that I used the large operating cystoscope, while my predecessor had only used the small inspection instrument.

The truth was revealed: these cases were due to spasm of the neck of the bladder, and a big bougie would cure them; it has cured many since.

> I was soon convinced by the arrival in the private ward of an anæmic and wasted lady with dysuria, who had consumed quarts of barley water and had had intensive alkalis and a vaccine. The pathological report of her turbid urine ran as follows: "The deposit shows a heavy deposit of pus cells and a few coliform bacilli. No tubercle bacilli present. Cultures show a free growth of streptococci. No *B. coli* grown after three days' incubation." Cystoscopy showed the usual appearances described above. Within three days the urine was clear, and she had remained well for four years.

The mechanical treatment of vesical and urethral spasm is the keynote in therapy. The dramatic cures obtained then fall into line with the cure of constipation after passage of the sigmoidoscope or by rectal bougies, and of cardiospasm by similar means. Treatment should therefore be directed to the prevention and cure of local spasm.

In the acute pyelitis with enlargement of the kidney so common in association with pregnancy, the indwelling ureteric catheter should be tried after simple measures have failed. If the catheter does not bring about improvement and operation is necessary, the renal pelvis should be approached through the renal substance without attempting to bring the kidney to the surface. Nephrectomy is rarely indicated.

Cases of pyelitis of vesical origin may be recognised by the history of neglect, absence of marked frequency, lower abdominal pain, and phosphaturia. The urine is neutral or alkaline, with the usual cloud of organisms. A strong smell is noticed by the patient or relatives, and is due to stagnation of urine.

TWO-STAGE MICTURITION.

The diagnosis can very often be established without the catheter or cystoscope, and cure can be obtained and recurrence prevented simply by two-stage micturition. Ask the patient to pass urine without straining, wait five minutes, and then ask him to try again; anything from one-half to several ounces is often obtained, *to the surprise of all concerned.* The residual urine so obtained is the origin of the chronicity of many urinary cases, the stale urine infecting the oncoming urine from the kidney and so creating a vicious circle. I owe this valuable procedure to Prof. Andrew Fullerton, and have found it of extreme value in early cases of enlarged prostate. We are *taught that the* prostate should be removed hen there is 2 oz. of residual urine, and almost the same line we read that a catheter should be oided lest infection be introduced. This para- xical situation is solved by two-stage micturition, peated every three hours during the day without raining; with no fluid intake after 8 P.M. Its nployment by those in charge of antenatal clinics ould diminish the urinary complications in preg- ncy, and it would make unnecessary the cathe- risation of something like 12 per cent. of hospital tients.[2]

---

[1] Cunningham, J. H., and Graves, R. C.: Surg., Gyn., and Obst., 1924, xxxix., 39.

In well-established cases of atonic bladder with veral ounces of residual urine, the important object avoiding overload and providing rest for the over- retched musculature can be attained by getting the tient to pass water by the two-stage method every ro hours, day and night. Benefit has usually llowed in three days, the bougie also being employed necessary. Two and a half hours is allowed to apse between micturition: after three days the riod is increased to three hours, and finally the tient is allowed to rest six hours at night. On per this looks a formidable procedure, but the scipline obtained is of value in the prevention of currence. These patients must always pass water two stages and at three-hourly intervals if they re to remain well and escape uræmia at 55.

Severe cases of atony may require six-hourly theterisation for the first few days. On occasion n indwelling catheter or suprapubic drainage has pplied the necessary bladder rest which, with bolition of sphincter spasm, spells cure.

MECHANICAL DISTENSION.

In late cases of "irritable bladder" and chronic stitis without retention, to the spasm of the internal phincter is added spasm of the whole bladder, and eatment has therefore to be directed to the abolition these conditions by the big bougie and by gradual echanical distension of the bladder itself. Daily y catheter and funnel a lotion is introduced into the adder and retained for ten minutes. I start with in 10,000 silver nitrate—that is, gr. 1 tablet of lver nitrate to one pint of distilled water, doubling e dose daily until stinging is experienced, then ontinuing with a lesser strength, normal saline being ept at hand to allay any pain produced by the lotion. ny bland lotion will do—it is the quantity intro- uced and not the antiseptic that matters. On the rst day pain may be experienced with half an ounce nd later with one ounce, and so on until at the end a fortnight four ounces are held, and then the ystitic patient, no longer losing her sleep, becomes nthusiastic. We are then ready to institute some odification of the drill for atonic bladder with the wo-stage method of micturition. I make no mention f bladder washes: it is bladder distension that ounts. Just as in orthopædic surgery manipulation ay start joint movement, so the amount of distension our ounces) necessary for cystoscopy will give the ecessary start to recovery. Over-distension, like ver-manipulation, brings disaster.

After the daily distension with lotion of increasing quantity, a straight penile or small Hegar bougie introduced to abolish spasm of the internal sphincter. vesical spasm is intense, pain may be allayed by aving one ounce of 5 per cent. old oil of cajaput in ive oil in the bladder. Gomenol or 10 per cent. mulsion of iodoform in tragacanth may be useful ternatives.

DIVORCE REFORM.

THE writer of a recent pamphlet on divorce reform suggests that the only way to compel immediate amendment of the law is for the medical profession to bring in a Bill of its own, "based solely on the grounds of the health and welfare of the nation, and avoiding all religious or controversial matters." The author, whose pseudonym indicates acquaintance with the legal side of matrimonial causes, paints a gloomy picture of the perjury, collusion, and connivance which, as he says, disgrace our divorce procedure. Here in brief are his proposed reforms. The following to be grounds for divorce—adultery, unnatural offences, non-consummation of marriage, chronic alcoholism, lunacy, syphilis, condemnation to penal servitude, and, finally, incompatibility of temperament. This last ground is to be discretionary, the judge to see the parties. Physical and moral cruelty would be included, also desertion, neglect of home and family, and dissolute living; where lunacy or disease is alleged, medical assessors to sit with the judge. The divorce, when granted, should be absolute, with no six months' delay; the office of King's Proctor should be abolished; the petitioner's adultery should be no bar to divorce; no damages should be awarded unless there are children, the damages to be paid into court and settled by the court on the children. The proceedings should be private and people of moderate means should be able to obtain a divorce in a county court for £30.

"The medical profession," writes the author, "to a man are in favour of reform, particularly on the ground of insanity." It is a cheery optimism which would suppose that the profession would be unanimous upon the contents of the proposed Bill or that "all religious or controversial matters" could be avoided.

MEDICAL NOTES FROM SPAIN.

A CORRESPONDENT in Madrid comments on some matters of interest to medical readers in present-day Spain.

A MUTUAL INSURANCE SCHEME.

Under the name "Previsión Médica Nacional" the medical profession in Spain, represented by various colleges which exist for purposes of medical defence, have elaborated a scheme of mutual assurance for the profession which it is hoped to bring into being before long. The aim is apparently to make it universal and obligatory, but there is no mention of any State supervision, though it is suggested that all doctors should join on leaving the universities after qualification. Its present activities are limited to two sections, health and life insurance, with four groups in each, differing only in the amount of their contributions and the benefits they may consequently expect. Everyone would have to join group 1 (the lowest) of the health section, and if he married the same in the life section. There will also be a benevolent fund taking 10 per cent. of the surplus funds and contributed to by the wealthier members of the profession which will deal with cases not otherwise eligible for benefit. The whole scheme is based on the practice of recognised insurance companies, but owing to the poverty of the majority of doctors in Spain the initial contributions and benefits are fixed very low.

INSPECTION OF PHARMACOBIOLOGICAL PRODUCTS.

Acting on a proposal of the Institute of Pharmacobiology, the Government has issued an order directing that all imported products in certain classes shall be liable to inspection by that body before being offered for sale. A very wide range of substances is included in the order, all vaccines, serums, and glandular preparations besides many drugs such as arsenobenzol and the like, ergot, oil of male fern and digitalis derivatives. Samples will be examined to ensure their purity and uniformity of composition before being admitted for sale in the country.

NAVAL SANITARY BOARD.

The reorganisation of the medical department of the Navy is being undertaken by the Minister of Marine and orders issued for the inspection of all matters of health and sanitation, whether as regards the personnel or the ships and naval buildings ashore. The instructions are under 12 heads, and include such matters as the inspection of hospital and hospital ships, the provision of a [illegible] upply ashore and afloat, and the establishment of venereal clinics.

---

THE DIET OF GERSON.

This diet, the advocacy of which on commercial lines has caused it to be regarded with suspicion by the medical profession in Spain, has nevertheless been tried by many, on account of the results obtained by Sauerbruch and Hermannsdorfer. Good results have been observed in pulmonary tuberculosis, but a tendency was noticed to subsequent relapses (*Nóvoa Santos, Carrasco Martinez*). The best effects were seen by the dermatologists in lupus and especially in lupus of the mucous surfaces. Bejarano, Covisa, Fernandez de la Portilla, Saínz de Aja have all written to this effect. Better results are obtained in children than in adults and the most striking in the case of endonasal lupus. The diet is modified by the substitution of similar Spanish foodstuff for those prescribed and fortified with vitamin producing elements such as fruit juices and cod-liver oil. Fernandez de la Portilla narrates a case of a woman who after 20 years' treatment for tuberculous manifestations in the larynx, ear, and nose, which always relapsed, has remained free for six and a half months without any other treatment than the diet.

The Second Congress of Oto-Rhino-Laryngology will open in Madrid on Sept. 27th. The subjects chosen for discussion are oto-sclerosis, ozæna, and scleroma, and the three presidents of sections will be Duel (New York), Costiniu (Bucharest), and Belinoff (Sofia). Prof. A. G. Tapia is the president of the organising committee in Madrid.

Appointments

Hull Royal Infirmary: CORBETT, C. H., M.D. Edin., F.R.C.S.E., Hon. Surgeon; PATRICK, A., M.B. Edin., F.R.C.S.E., Hon. Assistant Surgeon.

Certifying Surgeons under the Factory and Workshop Acts: BROADHURST, H. C., M.B., B.S. Durh. (Modbury, Devon); LEIGH, H. V., M.D., B.S. Durh. (Bridgend, Glamorgan); and MERYON, C. E., M.B., Ch.B. Edin. (Alresford).

Vacancies

Births, Marriages, and Deaths

BIRTHS.

BUTLER.—On March 17th, at "Crow's Nest," Orpington, [illegible] wife of M. Kempston Butler, L.D.S. R.C.S. Eng., of [illegible] daughter.

GILMER.—On March 18th, at Rodenbury, Hertford, the [illegible] of Dr. H. S. H. Gilmer, of a daughter.

MARSHALL.—On March 10th, at Bournemouth, the wife [illegible] Charles W. Marshall, M.D., of Sturminster Newton, Dors [illegible] of a daughter.

TOWNSEND.—On March 17th, at Welbeck-street, W., the w [illegible] of Dr. C. Geoffrey Townsend, of Mowbray, Beaconsfiel [illegible] Bucks, of a daughter.

DEATHS.

DISTIN.—On Friday, March 18th, at Moorlands, Paignt [illegible] Howard Distin, M.B. Lond., M.R.C.S., L.R.C.P., ag [illegible] 66 years.

HANNA.—On March 14th, at Exmouth, George Henry Han [illegible] M.D. Edin.

SMITH.—On March 17th, suddenly, in London, William Rob [illegible] Smith, Colonel, R.A.M.C. (ret.), Knight Bachelor, M. [illegible] D.Sc., LL.D., Emeritus Professor of Forensic Medicine [illegible] the University of London, Founder, President, and Princi [illegible] of the Royal Institute of Public Health, aged 82.

TURNER.—On March 18th, at 73, Onslow-gardens, Muswell H [illegible] Nathaniel Henry Turner, M.R.C.S., D.P.H. (formerly [illegible] Edgbaston and Highbury-grove, London), second son [illegible] the late Frederic Turner, of Nizels, Hildenborough, in [illegible] seventy-second year.

WHITCOMBE.—On March 13th, at Nice, of heart failure follow [illegible] an operation, Philip Percival Whitcombe, M.B. Lon [illegible] aged 73.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices [illegible] *Births, Marriages, and Deaths.*

MANCHESTER AND SALFORD HOSPITAL FOR SK [illegible] DISEASES.—At the annual meeting last week it was repor [illegible] that this institution which, when it was founded in 1 [illegible] treated some 600 patients in a year, is now treating 400 o [illegible] patients in a day, and that more than 100 forms of s [illegible] disease are being dealt with. The Manchester pu [illegible] health committee has accepted it as an approved cen [illegible] for the treatment of skin disease, and the out-patie [illegible] department is now entirely inadequate. Many patie [illegible] are paying towards the cost of their treatment, but m [illegible] than 90 per cent. of the men and 30 per cent. of the wo [illegible] are panel patients. Dr. Louis Savatard, one of the honor [illegible] physicians, pointed out that without a voluntary hospi [illegible] of this kind it would be difficult for panel patients suffer [illegible] from skin diseases to receive efficient treatment.
